EDITED UNDER THE DIRECTION OF THE EDITORIAL COMMITTEE
 HONORARY EDITORS : MAURICE DAVIDSON, M.D., and ERIC A. CROOK, M.Ch.
 ASSISTANT EDITOR : J. M. BROWNE KUTSCHBACH, M.B., D.P.H.

VOLUME THE THIRTY-NINTH.

SESSION 1945-46

OFFICERS :

- President*—Surgeon Rear-Admiral Sir GORDON GORDON-TAYLOR, K.B.E., C.B.
Immediate Past President—Major-General Sir HENRY TIDY, K.B.E.
Vice-Presidents—(Being the Presidents or duly appointed Representatives of the Sections the names of which are given in brackets)—GEORGE EDWARDS (Anæsthetics) ; NORMAN CAPON, M.D. (Disease in Children) ; A. DICKSON WRIGHT, M.S. (Clinical) ; W. A. POOL, M.R.C.V.S. (Comparative Medicine) ; M. SYDNEY THOMSON, M.D. (Dermatology) ; Sir WALTER LANGDON-BROWN, M.D. (Endocrinology) ; P. G. STOCK, C.B., F.R.C.P. (Epidemiology) ; E. N. ALLOTT, F.R.C.P. (Experimental Medicine and Therapeutics) ; Sir ARTHUR MACNALT, K.C.B., M.D. (History of Medicine) ; G. EWART MARTIN, F.R.C.S.Ed. (Laryngology) ; T. IZOD BENNETT, M.D. (Medicine) ; J. PURDON MARTIN, M.D. (Neurology) ; F. J. BROWNE, M.D. (Obstetrics and Gynæcology) ; LILIAN LINDSAY, L.D.S.E. (Odontology) ; P. E. H. ADAMS, F.R.C.S. (Ophthalmology) ; W. B. FOLEY, F.R.C.S. (Orthopædics) ; A. J. WRIGHT, F.R.C.S. (Otology) ; W. G. BARNARD, F.R.C.P. (Pathology) ; J. W. T. PATTERSON, M.D. (Physical Medicine) ; ERIC A. CROOK, M.Ch. (Proctology) ; G. W. B. JAMES, M.C., M.D. (Psychiatry) ; W. M. LEVITT, M.D. (Radiology) ; E. F. FINCH, M.S. (Surgery) ; A. WILFRID ADAMS, M.S. (Urology).
Honorary Treasurers—J. B. HUNTER, C.B.E., M.Ch. ; CHARLES NEWMAN, M.D.
Honorary Librarians—E. K. MARTIN, M.S. ; Brigadier T. C. HUNT.
Honorary Secretaries—CHARLES HARRIS, M.D. ; R. H. O. B. ROBINSON, F.R.C.S.
Honorary Editors—MAURICE DAVIDSON, M.D. ; ERIC A. CROOK, M.Ch.
Other Members of Council—ALICE BLOOMFIELD, F.R.C.S. ; L. R. BROSTER, O.B.E., M.Ch. ; E. A. COCKAYNE, D.M. ; V. ZACHARY COPE, M.S. ; DANIEL T. DAVIES, M.D. ; R. DAVIES-COLLEY, C.M.G., M.Ch. ; ANTHONY FEILING, M.D. ; A. T. FRIPP, F.R.C.S. ; Sir ARCHIBALD GRAY, C.B.E., M.D. ; AUBREY LEWIS, M.D. ; H. L. MARRIOTT, F.R.C.P. ; GEOFFREY MARSHALL, O.B.E., M.D. ; S. P. MEADOWS, M.D. ; J. D. ROLLESTON, M.D., A. C. ROXBURGH, M.D.

JOINT DISCUSSIONS

SECTION OF ORTHOPÆDICS WITH SECTION OF SURGERY

(JOINT DISCUSSION No. 1)

February 5, 1946

		PAGE	
		Section	Volume
TREATMENT OF ACUTE OSTEOMYELITIS WITH PENICILLIN ..	—	371-382	
Mr. R. Vaughan Hudson	—	371	
Dr. J. Trueta	—	377	
Mr. E. C. B. Butler	—	378	

SECTION OF MEDICINE WITH SECTION OF SURGERY

(JOINT DISCUSSION No. 2)

January 29, 1946

DIAGNOSIS AND TREATMENT OF CHRONIC CHOLECYSTITIS ..	—	495-500
Dr. Maurice Shaw	—	495
Dr. G. T. Calthrop	—	496
Mr. A. J. Gardham	—	498

SECTION OF NEUROLOGY WITH SECTION OF RADIOLOGY

(JOINT DISCUSSION No. 3)

February 15, 1946

RADIATION TREATMENT OF CEREBRAL TUMOURS ..	—	673-680
Dr. R. McWhirter	—	673
Mr. J. Pennybacker	—	676
Dr. Dorothy S. Russell [Summary]	—	678
Mr. J. Jackson Richmond	—	679
Dr. Frank Ellis, Mr. J. E. A. O'Connell	—	680

SECTION OF NEUROLOGY WITH SECTION OF ORTHOPÆDICS

(JOINT DISCUSSION No. 4)

March 7, 1946

DISCUSSION ON SPINAL CARIES WITH PARAPLEGIA ..	—	723-734
Professor H. J. Seddon	—	723
Mr. George L. Alexander	—	730

MYASTHENIA GRAVIS (TWO CASES)		
N. F. E. Burrows, B.M. (for W. G. Wyllie, M.D.)	25	591
SUBACUTE NEPHRITIS		
A. P. Norman, M.B. (for Donald Paterson, F.R.C.P.)	27	593
CHRONIC NEPHRITIS AND RENAL DWARFISM		
A. P. Norman, M.B. (for Donald Paterson, F.R.C.P.)	28	594
NEPHROSIS		
A. P. Norman, M.B. (for Donald Paterson, F.R.C.P.)	28	594
BRONCHIECTASIS INVOLVING ALL LOBES OF BOTH LUNGS TREATED BY LOBECTOMY AND MULTIPLE SEGMENTAL RESECTIONS		
Professor R. S. Pilcher, F.R.C.S.	28	594
MULTIPLE CYSTS OF THE RIGHT LUNG AND THE RIGHT BRONCHUS		
Professor R. S. Pilcher, F.R.C.S.	29	595
CALCIUM INFARCTION OF RENAL TUBULES IN INFANCY		
Pathological Specimens shown by Reginald Lightwood, M.D.	29	595

April 26, 1946

MULTIPLE ACHALASIA, VERTEBRAL DEFECTS AND RETARDED GROWTH		
John Apley, M.D., M.R.C.P. (by permission of Professor C. Bruce Perry)	31	689
HYPERTENSIVE RETINOPATHY IN A GIRL AGED 10 YEARS 11 MONTHS		
James Robertson, M.B., B.S. (by courtesy of Dr. R. Lightwood)	33	691
EXOPTHALMIC GOITRE IN A CHILD AGED 11 YEARS		
W. R. May, M.R.C.S., L.R.C.P. (by courtesy of Dr. Reginald Lightwood)	34	692
ACROCEPHALY-SYNDACTYL		
Beryl D. Corner, M.D.	34	692
PRIMARY HYPERPLASIA OF THE PARATHYROIDS IN A BOY AGED 8 YEARS		
R. J. Pugh, M.B., M.R.C.P. (for W. G. Wyllie, M.D., F.R.C.P.)	36	694
TUMOUR OF THE OPTIC CHIASM AND NERVE SHEATHS IN A GIRL AGED 2 YEARS 9 MONTHS, SHOWING SOME MANIFESTATIONS OF NEUROFIBROMATOSIS		
R. J. Pugh, M.B., M.R.C.P. (for Bernard Schlesinger, M.D., F.R.C.P.)	37	695
FAMILIAL HÆMOLYTIC ANÆMIA		
Charles Pinckney, F.R.C.P.	38	696
PNEUMOCOCCAL EMPYEMA—TREATED WITH PENICILLIN		
M. E. Hughes, M.B., B.S. (for H. M. M. Mackay, F.R.C.P.)	38	696
ARACHNODACTYL WITH AMYOPLASIA CONGENITA		
E. M. Kingsley-Pillers, M.B., B.Chir. (for H. M. M. Mackay, F.R.C.P.)	38	696
OSTEOMYELITIS AND NEPHRITIS		
R. M. Todd, M.D., M.R.C.P., D.C.H.	39	697
SUPPURATIVE ARTHRITIS TREATED BY ASPIRATION AND PENICILLIN REPLACEMENT (THREE CASES)		
A. D. Barlow, M.R.C.P.	39-40	697-698
MENINGOCOCCAL MENINGITIS WITH SUPPURATIVE ARTHRITIS		
Under D. Paterson, F.R.C.P.	39	697
SUPPURATIVE ARTHRITIS FOLLOWING BRONCHOPNEUMONIA		
Under W. G. Wyllie, F.R.C.P.	40	698
SUPPURATIVE ARTHRITIS OF RIGHT ELBOW FOLLOWING MASTOIDITIS		
Under B. Schlesinger, F.R.C.P.	40	698

May 25, 1946

SPONTANEOUS HYPOGLYCÆMIA IN INFANCY AND CHILDHOOD		
A. V. Neale, M.D.	40	698
THE TREATMENT OF CELIAC DISEASE WITH VITAMIN B COMPLEX AND LIVER EXTRACT		
Eric C. Allibone, M.D.	42	700

[May 18, 1945]

Observations on Certain Rheological Properties of Human Cervical Secretion

By A. F. CLIFT, F.R.C.S., M.R.C.O.G.

Late Assistant, Nuffield Department of Obstetrics and Gynæcology, University of Oxford

ABSTRACT.—The object of this Communication was to demonstrate two rheological properties of cervical secretion, namely, flow-elasticity and Spinnbarkeit. There is evidence that these properties undergo cyclic variation during the menstrual cycle and bear relation to ovulation, to penetrability by spermatozoa and to pregnancy. By means of the menstroscope, designed by Scott Blair, flow-elasticity or elastic recoil can be measured. It is found to be most marked at the time of ovulation when also the mucus is thin and transparent. Spinnbarkeit—the capacity of liquids to be drawn into threads—is also capable of accurate measurement by drawing away a coverslip placed on a blob of mucus which is drawn out into a long thread. It is also more marked at the time of ovulation and is almost absent in pregnancy. Plasticity and tack, two further properties of cervical mucus, were also discussed. It is believed that these tests will prove to be of value in diagnosis of ovulation and in the study of sterility.

A study of certain rheological properties of human cervical secretion was undertaken at the suggestion of G. W. Scott Blair, D.Sc., who had observed certain significant rheological phenomena in bovine cervical secretion when working on the problems of the time of ovulation and pregnancy diagnosis in cows, at the National Institute for Research in Dairying, Reading.

Scott Blair (1937) described an emptying-tube viscometer for use with rheologically complex materials. Scott Blair, Folley, Malpress and Coppen (1941) found that the viscous and elastic properties of bovine cervical secretions vary regularly during the œstrous cycle (fig. 1). The object of this communication is to direct attention to two recently recognized rheological properties of human cervical mucus, namely, *Flow-elasticity* and *Spinnbarkeit*; and to demonstrate the *Menstroscope*, an instrument for the accurate objective measurement of *Flow-elasticity*.

There is experimental evidence which suggests that the rheological properties of human cervical mucus undergo a cyclic variation in the menstrual cycle, and bear direct relation to ovulation, to penetrability of cervical mucus by spermatozoa, and to pregnancy.

Macroscopic examination of samples of human cervical secretion show marked variations in rheological properties according to the time in the menstrual cycle at which they are collected, e.g. at mid-cycle the secretion appears translucent and fluid; at other times of the cycle samples appear more viscid; in pregnancy the mucus is characteristically thick, sticky and gelatinous.

UROLOGICAL REFLECTIONS Sir Henry Wade, C.M.G., F.R.C.S.Ed.	49	751
---	----	-----

The Society does not hold itself in any way responsible for the statements made or the views put forward in the various papers.

of force needed to draw cervical mucus into a capillary tube, and the result was qualified as low, moderate or high.

Lamar, Shettles and Delfs (1940), using this method, found that there was no relation between "relative viscosity" and penetrability. This result surprised these workers and they suggested that "viscosity" might play a much larger part in penetrability than their results indicated; admitting that any approximation of the "relative viscosity" by this method was bound to be inexact.

As recently as September 1944 it was restated that no objective method for measuring "viscosity" of cervical mucus had yet been found (Viergiver and Pommerenke, 1944).

It is now possible to make accurate objective measurements of the rheological properties of human cervical secretion.

When considering a body secretion such as cervical mucus, we must remind ourselves that secretions are not true fluids—they are complex rheological systems (*see* Note 1)—and as such they are characterized by properties such as: Anomalous viscosity—Elasticity—Flow-elasticity—Spinnbarkeit—Thixotropy—Tack—Stickiness—Adhesiveness, &c.

A study of such physical properties is called Rheology—so called to save circumlocution. Rheology is "the study of flow and deformation of matter". Many of these phenomena are imperfectly understood and undoubtedly difficult to comprehend. Conceptions based on special properties of molecules, such as polarity and length, are theoretical aids to assist in understanding them.

Efforts are being made to replace rough subjective tests by more accurate objective measurements of these rheological properties. Cervical secretion is not a truly viscous fluid, and therefore cannot be said to have a viscosity (*see* Note 3). The characteristics of a true fluid are that it flows at a steady rate under constant pressure; and that when the pressure is increased, the rate of flow increases proportionately. With cervical secretion, the rate of flow is not constant at constant pressure: it increases as the stress rises, but also decreases with increasing deformation ("work-hardening") (*see* Note 1). Secretion belongs to materials that do not give straight-line flow-curves and therefore show anomalous viscosities (*see* Note 1).

Scott Blair *et al.* (1941) concluded, after examining many samples of bovine cervical mucus (a product of secretory columnar epithelium, as in the human), using the emptying-tube viscometer, that the results were not of sufficient accuracy, and too delicate and complicated for everyday use as a means of diagnosing ovulation.

FLOW-ELASTICITY (*see* Note 2)

While carrying out these experiments, Scott Blair *et al.* (1941) observed a property hitherto unrecognized in cervical mucus—Flow-elasticity, a property which undergoes cyclic variation throughout the oestrous cycle. They designed the oestroscope, by means of which oestrus can be detected in cows by measuring elastic recoil.

It occurred to us, that since ovulation normally occurs immediately after oestrus in cows, it might well be that the phenomenon flow-elasticity is associated directly with the oestrin secretion which normally accompanies ovulation (Séguy and Vimeux, 1933, correlated an increase in urinary folliculin with visual evidence of ovulation by inspection of the ovaries at laparotomy in women). We were therefore led to investigate the possibilities of flow-elasticity of human cervical secretion, as an indication of the time of ovulation in women.

These studies have led to the development of what appears to be a simple, reliable and rapid test for ovulation in women. The measurement of flow-elasticity may also prove useful in connexion with the physiology of the passage of the spermatozoa up the cervical canal, for when the elastic recoil is greatest (which appears to be at the time of ovulation) the mucus is thin and translucent—the type of mucus in which penetrability and longevity of spermatozoa are most marked (Lamar, Shettles and Delfs, 1940). It is suggested that in addition this measurement of elastic recoil might be of use as a simple tool in endocrine studies of ovarian dysfunction.

THE MENSTROSCOPE

This instrument was designed by G. W. Scott Blair for the measurement of flow-elasticity. When a material showing flow-elasticity is caused to flow along a tube, and the pressure is suddenly released, the material recoils back, towards its original position. This phenomenon was first described by Szegvari (1924) and named by him "Fließ-elastizität", which is generally translated "flow-elasticity". Ostwald and Malss observed it experimentally (1934). Scott Blair *et al.* (1941) first observed this property in bovine secretions. These workers found that the flow-elasticity phenomenon is much less affected by contamination of the sample than is "viscosity" and is also much more easily measured.

According to Moench (1934), the degree of penetrability of cervical mucus by spermatozoa seems to depend solely on the "viscosity" of the cervical secretion. The quantity of secretion, its pH and cellular content are factors of very much less importance in penetrability.

Lamar, Shettles and Delfs (1940), working at Johns Hopkins Hospital, have shown, using their micro-tubes and barrier-marker-bubble method, that spermatozoa penetrate

FIG. 1.—Variations in flow-elasticity of bovine cervical mucus during the oestrous cycle. Vertical broken line indicates observed oestrus and arrows denote service. Points marked with a circle are subject to a certain error due to inadequacy of sample. Clara and Flora became pregnant after the services indicated. (From *Biochem. J.*, 1941, 35, 1046. With kind permission of the Authors and the Editors of the *Biochemical Journal*.)

cervical mucus for an appreciable distance only when the mucus is translucent and thin; when the mucus is viscid (see Note 3), although the spermatozoa are strongly attracted to the mucus the viscosity impedes their upward progress—they quickly become enmeshed and devitalized.

A more analytical study of the rheological properties of cervical mucus is essential to a clearer understanding of the relation of these variations in consistency of cervical mucus to ovulation, to penetrability and to pregnancy.

"Viscosity" (see Note 3)

Robin (1848) observed the presence of "viscosity" in human cervical secretion in 1848 (many years before Sim invented his vaginal speculum). In 1925 Woodman and Hammond gave a detailed description of the variations in the physical properties of bovine cervical secretion during the oestrous cycle and pregnancy in cows.

Many workers on cervical mucus have realized the importance of "viscosity" in human cervical secretion in relation to ovulation and penetrability (Kurczok and Miller, 1928; Séguy and Vimeux, 1933; Séguy and Simmonet, 1933; Moench, 1934; Lamar, Shettles and Delfs, 1940; Viergiver and Pommerenke, 1944) but, until recently, no one has been able to measure accurately the "viscosity" of cervical secretion.

In the past "viscosity" was subjectively estimated roughly as thin or thick. Later, an attempt to measure "relative viscosity" (see Note 1) was made by estimating the amount

translucent and fluid—both are characterized by Spinnbarkeit and flow-elasticity—and both readily form tough bubbles on homogenization. In white of egg, Spinnbarkeit is more marked, elastic recoil less marked, than in mid-cycle cervical secretion.

One concludes that the molecular construction may well be somewhat similar in both materials. Penetrability of cervical mucus by spermatozoa probably depends on the molecular arrangement of the cervical secretion.

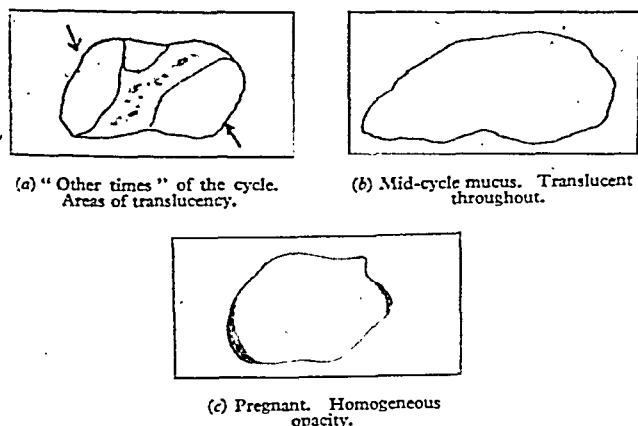

FIG. 4.—Diagrammatic representation of the macroscopic appearance of various samples of human cervical mucus (a, b, c).

FIG. 3.—Diagrammatic representation of Tack and Spinnbarkeit. A, Tack (as seen in pregnancy cervical mucus); B, Spinnbarkeit (as seen in mid-cycle cervical mucus).

It is reported that artificial insemination with semen mixed with white of egg is a more successful procedure (about 5%) than artificial insemination with semen alone (under 1%). Considering that thin and translucent cervical mucus, giving peak elastic recoil and maximum Spinnbarkeit (as is present at the time of ovulation), provides the optimum conditions for the height of penetrability of spermatozoa—and considering the therapeutic value of fresh white of egg in artificial insemination—it would be logical to suggest that a sample of cervical mucus with the above characteristics, obtained from a fecund donor at the time of ovulation, should be used together with semen for artificial insemination, i.e. to consider the soil (cervical mucus) as well as the seed (spermatozoa) in artificial insemination. Such a procedure is suggested in view of the disappointing results of artificial insemination with semen alone.

PLASTICITY

Plasticity is that property which enables a material to be deformed continuously and permanently without rupture, during the application of a force that exceeds the yield-value of the material.¹

Plasticity is a characteristic of pregnant cervical mucus.

A rheological law as applied to cervical mucus can be laid down as follows: "Plasticity predominates in pregnancy—Elasticity in non-pregnancy, especially at ovulation time."

¹ The yield-value is the pressure below which the material does not yield appreciably.

The menstroscope consists essentially of a graduated glass capillary tube of about 0.75 mm. bore, 10 cm. long and graduated in mm., with the glass drawn down to 3 mm. bore. One end fits on to a 2 c.c. Record syringe and a small side-tube 3 mm. bore is interposed between the tube and the syringe.

The test is carried out as follows: A dry sterile speculum is inserted into the vagina and a sample of cervical mucus is collected with a pair of long artery forceps—at mid-cycle a generous sample can usually be collected; at other times of the cycle, when the amount of mucus may be scanty, further secretion can be aspirated through a long glass pipette.

FIG. 2.—The menstroscope, for measuring flow-elasticity.

The collected sample of mucus is roughly homogenized by squeezing between two glass slides, one of the glass slides can be conveniently used for manipulating the blob of mucus. With the side-tube closed with a finger, mucus is drawn into the capillary tube until the meniscus reaches the 7 cm. mark. Keeping the side-tube closed, and the apparatus horizontal, the column of mucus is then slowly forced out of the capillary until the meniscus reaches the 4 cm. mark. At this point the finger is quickly removed from the side-tube, thus suddenly releasing the pressure on the column of mucus, the flow-elasticity of which causes the meniscus to recoil along the capillary. The amount of recoil in mm. is noted.

The menstroscope is made by Vann Bros. Ltd., and is made in perspex; the advantages over glass are that it is boilable and unbreakable in all normal conditions—the disadvantage is that care has to be taken which disinfectants are used, since some of them attack perspex.

In performing the elastic recoil test the following points should be strictly observed:

- (1) The cervix must be *healthy*—there must be no pathological tear, no marked erosion or endocervicitis.
- (2) Contamination with blood should be reduced to a minimum.
- (3) The specimen must be collected from the cervical canal—not from the vaginal vault or external cervical os.
- (4) Neither douching nor coitus must have taken place during the forty-eight hours preceding collection.
- (5) No antiseptics must be used in collecting the sample—only dry sterile instruments are used.
- (6) The elastic recoil test should be performed within twenty minutes of collection of the sample.

SPINNBARKEIT (Fibrosity)¹

This is the capacity of liquids to be drawn into threads. White of egg shows this property to a marked degree. Erbring (1936) studied Spinnbarkeit in detail; he takes a narrow capillary tube, with a conical mouth into which he sucks the material—he then withdraws the tube at a constant rate and measures the maximum length of the fibre which can be produced before rupture occurs. Over a considerable range, the length of the thread which can be drawn is generally proportional to the speed of drawing, which therefore should be kept as constant as possible. Erbring (1936) finds that there is no universal connexion between the maximum length of the fibre under standard conditions, and either viscosity or surface tension. Spinnbarkeit, capable of accurate objective measurement, is a property of cervical mucus, but it is present only to a marked degree when flow-elasticity is at its height, i.e. in mid-cycle samples. It appears to be directly related to ovulation and to the type of mucus in which penetrability by spermatozoa is greatest. Spinnbarkeit is only seen to a much less degree at other times of the menstrual cycle, and is more or less absent in pregnancy.

The test is carried out by drawing away a coverslip placed on a blob of mucus—the mucus is drawn into a long thread. At present we are estimating Spinnbarkeit by measuring the length of the thread in cm. The construction of an instrument for accurate objective measurement (such as that used by Erbring) is under consideration.

It is an interesting observation to note the marked similarity of the rheological properties of mid-cycle cervical secretion and fresh white of egg. Both these substances appear

¹ Rheologists are at present discussing a more suitable English term for this property.

The number of leucocytes was determined by microscopic examination.

Recoil values determined in samples from three subjects at intervals over a period covering 3, 2, 2, menstrual cycles respectively are shown plotted in fig. 5.

It is clear that the flow-elasticity of the cervical mucus varies regularly during the menstrual cycle, rising to a maximum about the time of ovulation. It is desirable to investigate the way in which the elastic recoil values vary day by day during the mid-cycle. Facilities for such an experiment have unfortunately not yet been available but it is hoped that this may be done in the near future.

Two of the women became pregnant during observation, the periodicity in elastic recoil immediately disappeared and the values remained at a low level.

The periodicity in the flow-elasticity of the cervical mucus, correlated with the time of the mid-cycle, appeared to afford a basis for an objective method of diagnosis of ovulation, particularly as this property can be measured so rapidly and easily. Since failure of ovulation is one of the causes of functional sterility, there is need of a simple, yet reliable method for the detection of ovulation. In order, therefore, to investigate the

FIG. 5.—Variations in flow-elasticity of human cervical mucus during the menstrual cycle and in pregnancy. Points marked with a circle are subject to a certain error due to inadequacy of sample. C. S. and A. M. were subsequently proved to be pregnant.

value of flow-elasticity measurements as a practical method for the diagnosis of ovulation, numerous determinations have been made on samples from women in various phases of the menstrual cycle.

Fig. 6 summarizes the results of tests on 26 women.

Comparing the figures it is clear that the elastic recoil values for samples taken about the time of ovulation are significantly higher than for samples taken at other times of the cycle or in pregnancy. On the basis of our data, therefore, it may be concluded

FIG. 6.—Relation between the amount of cervical mucus, its elastic recoil, Spinnbarkeit, number of leucocytes contained and the time in the menstrual cycle. These curves are based on observations on 26 women with normal menstrual cycles.

TACK

Tack (a form of stickiness) is another independent property of cervical mucus, but is only seen to a marked degree in pregnant samples. All samples of cervical mucus show stickiness to some degree, but tack is a particular form of stickiness.

In practice, tack is measured by quickly drawing away a coverslip from a blob of mucus placed on a glass slide. The mucus does not form into long threads, but the whole surface of the blob adheres to the coverslip and can be drawn only a slight distance away from the glass slide—about a cm. or two.

A more exact measurement can be made of this property by a specially contrived apparatus ("The Tackmeter", see Green, 1941).

Examination of the sample under the microscope after performing the test shows a tree-like pattern.

OBSERVATIONS ON 143 COLLECTED SAMPLES OF HUMAN CERVICAL SECRETION,
NON-PREGNANT AND PREGNANT

A. Mid-cycle Samples (11 of 13 Samples).

Quantity: Abundant.

Appearance: Translucent throughout, optically clear—very glassy.

Consistency: "Runny" (not cohesive or tacky).

Cellular content: Scarcity of cells, and these cells show a movement (not Brownian) due to the viscosity of the fluid.

Tough bubbles form very readily when homogenizing the secretion between two glass slides—these bubbles are difficult to break up.

Spinnbarkeit: Very marked—mucus can be drawn into very long threads 10 to 13 cm. long.

Elastic recoil: Very marked—av. 30 mm. and recoil is "lightning" in speed.

All the above properties were present to a marked degree in 11 samples collected at the mid-cycle. These properties were more or less absent in samples collected at other times of the cycle—and in pregnancy.

B. Post-menstrual Samples.

Quantity: Moderate.

Appearance: Translucent areas, with only tiny specks of opacity (i.e. not homogeneously opaque).

Consistency: Not as "runny"—more cohesive than at mid-cycle, but not tacky or but slightly so.

Cellular content: Moderate—no cell movement seen.

Tough bubbles: Do not form on homogenization.

Spinnbarkeit: Not present—or but slightly so (1 cm.).

Elastic recoil: Av. 10 mm.

C. Premenstrual Samples.

Quantity: Scanty.

Appearance: Translucent areas with small areas of opacity (not homogeneously opaque).

Consistency: Not as "runny"—more cohesive than at mid-cycle. Not tacky or but slightly so.

Cellular content: Moderate to abundant—no movement seen.

Tough bubbles: Do not form on homogenization.

Spinnbarkeit: Not present or but slightly so.

Elastic recoil: Av. 8 mm.

D. Pregnant Samples.

Appearance: As early as the 6th to 7th week of pregnancy (seven samples) the secretion shows a characteristic homogeneous light opacity—i.e. it loses its translucency throughout. Later in pregnancy this opacity becomes more pronounced.

Consistency: Cohesive—one piece—it tends to hold together. It is thick and sticky (not "runny") and shows characteristic tackiness.

Cellular content: Very abundant, no movement seen.

Tough bubbles: Do not form on homogenization.

Spinnbarkeit: Is absent or only slightly present.

Elastic recoil: 6th to 7th week to 10th week, value may be up to 6 mm. and recoil is slow.

After 10th week the mucus is difficult to draw into the menstroscope—recoil is absent.

RESULTS

Our results, at first, made no sense whatsoever. It was only after some months of work, that we realized how important it was to deal only with samples collected from the healthy cervix, in order to study first principles.

In all, the cervical mucus of 26 women showing normal cycles has been studied. Seven of these individuals have been seen more than once and 3 studied for at least one cycle.

An attempt was made to correlate the amount of mucus secreted, macroscopic appearance, elastic recoil, Spinnbarkeit and the number of leucocytes contained.

Mucus was judged to be (1) scant, (2) moderate, (3) abundant, at the time of collection.

Elastic recoil was determined by the menstroscope, Spinnbarkeit was measured in cm.

that the elastic recoil value of 25 mm. and upwards means that when the sample was taken, the woman concerned was about the time of ovulation.

A feasible explanation of the marked rheological changes in cervical mucus about the time of ovulation is that they are brought about by the direct action of the ovary through folliculin in the blood-stream, on the cervical mucus. It is known that follicular fluid dissolves cervical mucus. (It is of interest to note that Rowlands and MacLean were unable to show that hyaluronidase of semen dissolves the mucoprotein of cervical secretion.)

These observations are presented because they may point the way for further investigation.

SUMMARY

(1) "Viscosity" of human cervical secretion is discussed. Cervical mucus is not a truly viscous fluid and cannot be said to have a viscosity. Its changing "viscosity" (anomalous viscous behaviour) with varying stress and strain can be effectively measured in a Scott Blair emptying-tube viscometer, but the apparatus is too delicate and complicated to be of practical everyday use as a test for ovulation or pregnancy.

(2) Rheological properties—*Flow-elasticity* and *Spinnbarkeit*—hitherto unrecognized in human cervical secretion, are described. Both phenomena occur to a marked degree only in mid-cycle samples, and therefore form the basis for a rheological test for ovulation in woman. These properties are maximum only in "thin and translucent" samples, i.e. when penetrability and longevity of spermatozoa are greatest. These phenomena are absent in pregnancy samples.

(3) Means of accurate objective measurement of flow-elasticity (*the menstroscope*) and *Spinnbarkeit* are described. These methods are simple and rapid and more reliable than methods used to estimate "viscosity" and "relative viscosity".

(4) A rheological test for ovulation in woman is described—namely the sample of cervical mucus is "runny"; homogeneously translucent; elastic recoil and *Spinnbarkeit* are maximum; tough bubbles, which are difficult to break up, readily form on homogenizing the sample; cellular content is minimal, and these few cells show movement typical of mid-cycle samples.

(5) Considering the molecular construction of cervical mucus, it is suggested that the addition of donated cervical mucus (characterized by maximum elastic recoil and *Spinnbarkeit*) to semen, might be used with advantage in artificial insemination of cases of cervical hostility (absence of suitable cervical secretion).

(6) Tack is described—a property characteristic of pregnancy cervical mucus.

(7) A rheological test for pregnancy in woman is described—namely, the sample of cervical mucus is thick (not "runny"); homogeneously opaque; the mucus is difficult to draw into the menstroscope; there is more or less absence of elastic recoil and *Spinnbarkeit*; tough bubbles do not form on homogenizing the sample; and tack is characteristically present (the above description applies to samples as early as the seventh week of pregnancy).

(8) It is believed that the described rheological phenomena and tests should prove of practical value in the recognition of ovulation and anovulatory cycles; in the investigation and treatment of cases of cervical hostility; as a useful tool in endocrinology of ovarian dysfunction; and as accessory tests for pregnancy.

This work was carried out in the Nuffield department of Obstetrics and Gynaecology under Professor Chassar Moir, to whom I wish to express my appreciation for help and encouragement, and I wish particularly to thank G. W. Scott Blair, D.Sc., rheologist, for freely giving of his time and valuable scientific knowledge. I would stress that this investigation forms an admirable example of the need for co-operation between workers trained in different fields. Results would have been meagre without the co-operation of trained rheologists and medical personnel. I am also grateful to Mr. John Stallworthy, Mr. Scott Russell, Dr. Fynn and Dr. Dorothy Newell for providing mucus samples from patients.

NOTES BY G. W. SCOTT BLAIR, D.Sc.

NOTE 1.—Anomalous viscous behaviour is the general term for any "runny" material that is not a true fluid. There are many kinds of anomaly, the principal types being:

(a) Non-Newtonian fluids ("Pseudo-plastic" has almost the same meaning).—These start to flow at the smallest pressures, i.e. have no yield-value and are therefore not "plastic". The rate of flow is not proportional to pressure but increases either more or less rapidly than would a true fluid. The former case is the commoner (see Graph 1).

A complicating factor is that in practice, such curves cannot be directly obtained for spinnbar materials because the ratio of pressure (stress) to rate of flow not only falls with rising stress but increases with increasing deformation (work-hardening). This is very important. Hence we have Graph 2.

(b) Plastic behaviour.—Up to a certain stress (the yield-value) there is no flow. Above this flow is often proportional to the (stress minus yield-value), i.e. the line is straight. (The bottom part is usually anomalous and is therefore dotted in. The yield-value is generally got by extending the experimental straight line to the stress axis, but there are other yield-values defined in other ways) (see Graph 1).

Graph 1.—To illustrate the meaning of certain rheological terms.

Graph 2.—To illustrate a type of work-hardening.

Mobility is defined as $\frac{\text{rate of flow}}{(\text{stress minus yield-value})}$ and should be used only to mean this. Its reciprocal, $\frac{(\text{stress minus yield-value})}{\text{rate of flow}}$ is called "stiffness" or "pseudo-viscosity". The reciprocal

of viscosity (of a true fluid) (i.e. $\frac{\text{rate of flow}}{\text{stress}}$) is called "fluidity". These terms should only be used in the strict sense. English rheologists (not American) still use "consistency" as a general term for "general viscosity".

Relative viscosity (of a true fluid) simply means the number of times a liquid is more viscous than water, e.g. an oil has a viscosity at 25° C. of 50 centipoises. Water at 25° is almost exactly 1 c.p., hence "relative viscosity" of oil is "50".

Note 2.—Flow elasticity is usually paralleled by the onset of Spinnbarkeit, a reduced consistency and perhaps a fall in nitrogen content.

Note 3.—The use of "viscosity" (or "fluidity") in anomalous systems.—Some rheologists agree to speak of a viscosity defined for arbitrary stress-strain conditions but all are agreed that "the viscosity" has no meaning. The Americans tend to use "consistency" to mean "a viscosity" but this use is not popular in England. The term "viscid" has no special sense for rheologists.

Professor Chassar Moir assured members that the changes in the cervical secretion—some of which could be so clearly and easily demonstrated by the "menstroscope"—were of a very real nature.

Dr. G. W. Scott Blair: Those unfamiliar with rheology are apt to be rather overwhelmed by the abundance of rheological properties. In fact, it is all to the good that most biological "fluids" are not "true fluids", i.e. do not flow at a constant rate under steady pressure, the rate being proportional to the applied pressure. "True fluids" would only give us one flow property (viscosity) to correlate with the factors we wish to study. As it is, there are many factors which can be correlated; but it is naturally important that they should be clearly distinguished and adequately measured.

The measurement of flow-elasticity (or Spinnbarkeit which is often associated with it) has given us a good practical test for oestrus in the cow and a study of more complex rheological properties of cervical secretions an interesting, though not yet reliable, correlation with bovine pregnancy.

Through the skill and perseverance of Mr. Cliff it now seems likely that similar methods may be of use in detecting ovulation and pregnancy in the human.

Some New Facts Concerning the Prognosis and Treatment of Carcinoma of Cervix by Radiation

By MALCOLM DONALDSON, F.R.C.S., F.R.C.O.G.

In 1922 the late Dr. Canti and I were interested in the problem of how radium brought about the destruction of cancer cells in carcinoma of the cervix. We cut sections before and after treatment and discovered some obvious changes [1], but did not get very far in the solution of the problem. At that time, the late Dr. Strangeways was doing some of the earliest *quantitative* work on the biological effects produced by X-ray. He used fibroblasts in tissue culture. We then joined forces [4] and Strangeways and his collaborators did some pioneer work on the subject [2]. This type of work has continued at the Strangeways Research Laboratories ever since, and recently Dr. Spear and Dr. Glücksmann started their systematic work on the effects of irradiation on tissue *in vivo* and have now shown that similar quantitative methods are applicable to growth under these conditions.

I do not propose to trace all the stages of their investigations which eventually brought them to their work on human malignant tumours [3, 5].

In treating carcinoma of the cervix by radiotherapy for many years, certain puzzling questions arose, why, for example, among Stage 1 cases should only 50% do well and the other 50% do badly? Again, the majority of advanced cases ended fatally within a few months and the growth did not clear up even close to the radium applicator, although it was obvious that the malignant cells locally got as much irradiation as the cells in the early and successfully treated cases. It is also true that occasionally an advanced case which had been given a small dose, possibly as a placebo, cleared up and lived for years.

It was easy to say that some growths are more radio-sensitive than others, but that did not help to advance the subject. I think it is fair to say that Spear and Glücksmann are the first to throw any real light on this very important subject of radio-sensitivity.

The first point that they have proved is that with the "Stockholm Technique" and its modifications the most "radio-curable" are the *well-differentiated growths* and not the *undifferentiated growths*. I use the word radio-curable to mean the disappearance of carcinoma cells in sections taken after treatment. This came as a surprise to some of us who had observed large hypertrophic growths (which were assumed to be undifferentiated) disappear macroscopically in a few weeks. Some of these tumours in fact are differentiated, some undifferentiated, and it has now been found that it is the anaplastic type of growth which on section more frequently shows a persistence of viable malignant cells after irradiation.

It is important to be quite clear as to what we mean by the terms Differentiated and Undifferentiated growths. In "Differentiated" growths, which we will call Anaplastic Squamous (AS), the cells when young resemble normal basal cells, but when growing old they either undergo normal keratinization giving rise to typical cell nests or they undergo abnormal keratinization giving rise to an aggregation of basal cells round a necrotic core (fig. 1).

In "Undifferentiated" tumours called Anaplastic Parakeratotic (AP), the cells when young are capable of active mitosis, but degenerate as they get older by a process of cytoplasmic condensation (parakeratosis) or by nuclear disintegration (fig. 2).

If a large number of differentiated and undifferentiated tumours are classified according to the stage of the disease, when first seen it will be found that the differentiated tumours predominate in the early stages, and the undifferentiated tumours in the late stages.

TABLE I.—STAGE DISTRIBUTION AMONG TUMOUR TYPES.

	Differentiated (AS type)	Undifferentiated (AP type)	Columnar cell tumours
Stage 1 ...	50%	44%	6%
" 2 ...	34%	62%	4%
" 3 ...	23%	71%	6%
" 4 ...	12%	82%	6%

Why are there more differentiated growths in Stages 1 and 2 than in Stages 3 and 4? It is tempting to suggest that a well-differentiated growth if left untreated becomes an un-

FIG. 1. $\times 550$.

RC = resting cell. DF = differentiating cell.
M = mitotic cell.

Shows some young undifferentiated cells with small amount of cytoplasm, darkly stained nuclei, and absence of distinct cell wall. The section also contains some more mature cells which show differentiation and the nuclei are paler, the cytoplasm is eosinophilic and there is a clearly defined cell wall.

FIG. 2. $\times 550$.

Resting (RC) and mitotic cells (M) only. Shows cells which all have dark nuclei, and there are no cells showing typical differentiation.

FIG. 2.—The four cell types:

RC = resting cells } viable.
M = mitotic cells }
DF = differentiating cells } non-viable.
DG = degenerating cells }

FIG. 3. $\times 700$.

differentiated growth. If this were so, it would be expected that there would be a longer history in undifferentiated growths than in differentiated growths in the same stage.

It is impossible to get an accurate history of duration of the disease, but judging from the length of time irregular bleeding has continued there is no evidence of any difference in the *average* duration of symptoms between the two types of tumour in the same stage though a few growths give quite long histories. It is also interesting to note that the average history of Stage 1 and Stage 4 is 4.2 months and 7.5 months respectively. It seems, therefore, that a tumour staged as 4 is more often one which has grown quickly than one which has been slowly growing for a long time, but it still remains to be explained why a quickly growing tumour does not give rise to symptoms in the early stages and thus attract attention.

Glücksmann has studied pre-radiation sections of 346 tumours in which a five-years' follow-up was possible, and found that of the 87 differentiated tumours 28 patients lived for five years or more = 32%, but of the 259 undifferentiated tumours only 40 lived for five years = 15%.

FIG. 4.—Day 0: pre-radiation biopsy showing a young area. $\times 175$.

FIG. 5.—Day 13: biopsy after two irradiations (no change). $\times 175$.

FIG. 6.—Day 35: biopsy after three irradiations (no change). $\times 175$.

FIG. 7.—Day 179: biopsy is practically indistinguishable from the pre-radiation specimen when the young areas are examined. $\times 175$.

FIG. 8.—Quantitative histological chart of counts from AP tumour shown in figs. 4 to 7.

— Resting cells.
 - - - Differentiating cells.
 . . . Degenerating cells.
 - . . Mitotic cells.

There are only minor variations in the cell counts throughout the period of observation. Death occurred at month 7. Clinically this was considered at first unfavourable, then as doing well, but finally as unfavourable.

FIG. 8.

FIG. 9.—Day 0: pre-radiation biopsy showing a young area of growth. $\times 95$.

FIG. 10.—Day 2: marked increase in cell size and in the number of differentiating cells. $\times 95$.

FIG. 11.—Day 7: further increase in cell size; reduction in the number of resting cells. $\times 95$.

FIG. 12.—Day 11: only non-viable malignant cells left. $\times 95$.

FIG. 13.—Quantitative histological chart of case shown in figs. 9 to 12. There is a rapid fall in the numbers of viable cells (i.e. resting and mitotic) and a rise in the numbers of non-viable cells (i.e. differentiating and degenerating) up to Day 6. Then differentiating cells begin to break down and degenerate (— line falls and - - - line rises). [From *Brit. J. Radiol.*, 1941, 14, 192.]

FIG. 14.—An AP type tumour, clinical Stage 3, seventy-two-hour treatment, showing slow but favourable type of response to treatment at biopsy site.

TABLE II.—THE FIVE-YEAR SURVIVAL RATES FOR 346 PATIENTS WITH TUMOURS OF THE AP OR AS TYPE.

Clinical stage	AP tumours			AS tumours		
	No. of cases	Five-year survivors		No. of cases	Five-year survivors	
1 ...	15	6	40%	15	7	46%
2 ...	48	11	23%	27	9	33%
3 ...	107	18	16%	32	11	34%
4 ...	80	5	5%	13	1	7%
Totals	250	40	15%	87	28	32%

The table shows quite clearly that tumours of the AP type respond less well to radiation treatment (by the technique here used) than those of the AS type, the difference being most marked in clinical Stage 3, where the proportion of patients with AS tumours who survive five years is more than twice the corresponding figure for patients with AP tumours.

At first sight it might be thought that the greater number of well-differentiated tumours in Stages 1 and 2 would account for the better results in well-differentiated tumours, but a glance at Table II shows that in the same stage the well-differentiated do better than the undifferentiated. Further it might be thought that the patients with AP tumours in Stage 3 did badly because these growths had already given rise to metastases. This may be true in some cases but the fact that sections taken from the primary growth after treatment still show growth to be present, and that the recurrence occurs *within* the irradiated area proves that there must be a difference in the reaction of these tumours to irradiation compared with the AS tumours.

In addition to being able to state whether a tumour is likely to be "radio-curable" (i.e. that the tumour is not likely to recur in the treated area) by a study of the pre-radiation biopsy, Glücksmann has worked out a method whereby it is possible to make a more accurate prognosis of the final results of the treatment on the local growth in any given case. *This is done by a quantitative study of post-radiation sections for comparison with the pre-radiation section.* This method has been worked out on sections taken from many institutions, and among these is Mount Vernon Hospital. I send sections to Dr. Glücksmann at Cambridge who works out the prognosis, and I go up about once a quarter with the clinical notes of the case to compare the results.

The following is the method by which the tumour response is judged.

Sections are always taken from the growing edge of the tumour. This is an important point, as, if sections are taken from the centre of the growth, the cells may be too necrotic to give results of any value. I may add that Dr. Glücksmann has taken many sections from the growing edge of different parts of the same tumour, where a cancer has been excised, and the slides have shown the same picture in each selected portion of the tumour.

Having obtained a pre-radiation section, percentage counts are made of the following four types of cells:

A. *Resting cells.*—These are stock cells which are not differentiating and not dividing, but which retain the power to divide (fig. 2).

B. *Mitotic cells.*—These need no definition. A cell is counted as a dividing cell whatever the stage of mitosis.

C. *Differentiating cells.*—These are recognized by an alteration in the structure of the cytoplasm, which becomes eosinophilic and there is a distinct cell wall. This alteration may proceed to parakeratosis or to true keratinization. Either process renders the cell non-viable (fig. 1).

D. *Degenerating cells.*—These are moribund cells showing various forms of nuclear disintegration (fig. 3).

Biopsies are then taken on at least two occasions after the treatment has begun and the percentage counts made in the same way. All the counts are then plotted on a graph against time on a convenient scale.

Two series of micrographs will illustrate the method in practice. The first series shows histological appearance of serial biopsies from an unsuccessfully treated tumour (figs. 4, 5, 6, 7). Fig. 8 shows a quantitative histological chart made from counts in the above examples.

The second series illustrates a successfully irradiated tumour (figs. 9, 10, 11, 12).

Fig. 13 shows a quantitative histological chart made from counts in figs. 9-12.

It is now necessary to see how the prognosis given by the histologist within three weeks of the treatment, and which depends on the reaction of the primary growth as revealed by these cell counts, agrees with the prognosis given by the clinician who sees the patient from time to time in the "follow-up". In many cases the clinician is too optimistic in the early months, as he sees the growth disappear macroscopically, but after two years the difference between the two prognoses has disappeared in most cases as will be seen in Table III.

TABLE III.—COMPARISON OF HISTOLOGICAL* AND CLINICAL EVALUATION OF TREATMENT RESULTS AT INTERVALS IN A SERIES OF 150 CASES OF UTERINE CARCINOMA.

		1-4	5-8	Months 9-12	13-24	Over 24
Agreements (in number of cases)		82	104	108	111	111
Disagreements	" "	68	42	30	38	25†
No report	" "	0	4	3	1	14‡

* The histological evaluation is made within three weeks of beginning treatment.

† Includes 9 patients known to have had insufficient treatment in affected regions at a distance from the biopsy site.

‡ Among the "14 no reports" for "over 2 years" column are a number of patients not yet two years from treatment.

If, as I believe, this method is of value in giving a prognosis, then we should be able to use such curves in judging between the effect of different techniques without waiting for five years in order to compare the results of such methods of treatment. Realizing that the undifferentiated cases do badly, I decided to try a modified technique, and have now as a beginning treated 38 cases using the same amount of radium, the same number of hours, but a continuous dose instead of interrupted applications. It is too early to make any statement as to the clinical results but the histological picture suggests a definite improvement.

So far I have tried to point out the importance of the histology in making a prognosis in case of carcinoma of the cervix treated by irradiation, and the value of such observations in planning new techniques. This does not explain all our failures, there are many other factors which must be investigated and one important factor is the distribution of the irradiation. The ideal to be aimed at is an equal distribution of irradiation over the whole area affected by the growth. Dr. Neary has studied this problem very carefully and in 1943 published a paper in the *British Journal of Radiology*, 16, 225-233, and has constructed an applicator embodying these ideas. An applicator embodying some of these principles has also been designed by Mr. Blomfield with the vaginal radium in the middle line. I do not think that his design will give a good distribution of the radiation although it will be more adaptable to different-sized vaginae.

Dr. G. J. Neary stated that he had shown in his paper that the radium in the uterus should be concentrated as far as possible near the fundus and that the radium in the vagina should be placed at the mid-line. Further, the amount of this vaginal radium should be very considerably increased in order to produce an appreciable improvement in the dose at the more outlying region of spread of the disease in the pelvis. The increased amount of radium in the vagina necessitates the use of heavy absorbing screens of platinum or similar metals in order to protect structures such as the rectum from excessive irradiation.

An applicator embodying these principles has now been constructed (with the aid of a grant from the Medical Research Council) to Dr. Neary's design and the work was executed by Mr. Powell and Mr. Aldridge of Messrs. Johnson, Matthey & Co. Ltd. It must be emphasized that there is a wide latitude in the actual design decided on. The applicator referred to here is only one possible version and is intended as an experiment and, if successful, a range of applicators of different sizes will be used. It is in three sections; the uterine tube of adjustable length contains 70 mg. of radium and is inserted first. Next the upper half of the vaginal portion is inserted, followed by the lower half. The whole system is then simply locked together whereupon the vaginal radium consisting of two sources of 140 mg. each is inserted. The total treatment time is to be about 72 hours. The transverse diameter of the vaginal portion of the applicator is 4 cm., the antero-posterior diameter 3½ cm. The diameter of the uterine tube is 7 mm., the length may be adjusted between 3.3 and 5.3 cm.

The dose around the internal os and parametria is 7,000 to 8,000 r (fig. 1). The maximum dose at the pelvic wall (fig. 1) is 5,400 r while the average dose over a 5 cm. length of the pelvic wall around B is 4,700 r. The average dose to the posterior vaginal wall is

about 4,500 r (rectum, not more than 4,000 r). Figs. 1 and 2 show a comparison of the dosage with that in the average Marie Curie technique, deduced from the data of Mayneord and Honeybourne (*American Journal Roentgenology and Radium Therapy*, 45, 235-249, 1941). This shows a transverse section across the pelvis at the level of the internal os. The very much improved lateral extension of the radiation field of the new applicator is clear, the pelvic wall dose being 5,400 r instead of 2,000 r in the Marie Curie technique.

FIG. 1.

FIG. 2.

Dosage in transverse section through pelvis at level of internal os, viewed from front.
FIG. 1: New applicator. FIG. 2: Marie Curie technique. Numbers refer to thousands of r units.
(A) (parametrium) is 2 cm. from mid-line; (B) (pelvic wall) is 5 cm. from mid-line.

The applicator is fixed and supported in position by a strong harness attached by straps and belt to the patient. (*Brit. J. Radiol.*, 1943, 16, 225.)

Mr. Anthony Green: In certain cases of carcinoma of the cervix the main point is the increased dose obtained in the outer part of the broad ligament, and Neary's appliance is an important advance. The disadvantages of the applicator would appear to be first, that 70 mg. of radium is concentrated against a very small section of the interior of the uterus, thus raising the dosage in r units to a level much greater than has ever been done before. It is possible that this may be dangerous, and produce local uterine radionecrosis. Only the results can show whether this is produced or not. A second disadvantage is that the applicator may not be useful for all types of carcinoma of the cervix. The large fungating carcinoma of the cervix, filling a large proportion of the vault and the contracting eroding type of carcinoma or a small vagina may not permit the applicator to be used. Despite the increased range of the radium, there is still a limit to its efficacy in terms of distance from the mid-line, and although early Group 2 cases will undoubtedly be more effectively treated if they are suitable, extension well out toward the pelvic wall will still need supplementary treatment by X-ray therapy to raise the dosage to the required level.

It is not in the best interest of the patient to standardize a technique for all kinds of growth, having in mind the fact that they vary considerably, from the stenosing contracting type to the large cauliflower mass, and there is a variable extension of growth into the broad ligament on one or other side or both. It is clear that a mass in the broad ligament of large dimensions or near the lateral pelvic wall is beyond the effective range of radium however skilfully it is applied, and whatever intra-uterine and intra-vaginal apparatus may be used. The possible exception to this is a highly radio-sensitive growth, which, however, is found in the minority of cases.

Principles of treatment.—It is better to use a moderate dose of X-rays to shrink down a large growth to such a size that it brings it within the effective range of the radium, and secondly it is an obvious advantage to shrink down the primary growth if it is bleeding profusely, and causing a foul filthy condition of the vaginal vault.

A disadvantage of preliminary X-rays is that in a few cases the os is inclined to scar, and it is difficult to introduce the radium, but this can be readily overcome: The cervical lumen can be maintained artificially and more than four weeks' interval between X-rays and radium should be avoided. On the other hand, one has to balance the advantage that the os is more readily located when certain filthy bleeding growths are shrunken down and consequently the lumen is more visible. It has been claimed by some that even the large growths do shrink considerably after the first and second radium treatment thus bringing the outer part of the growth within the range of the radium for its second or third application.

This is a misleading statement because it is clear that the outer part of the growth as it shrinks has only received its contribution of dose close to the radium, possibly on the third application only, and is unequally dosed.

With regard to the application of radium all types of local growths so far as the cervix are concerned do not lend themselves equally well to exactly the same technique of radium treatment and a strong plea is made for individualization of the radium planning so that the best possible distribution of radium is used for a particular type of growth being treated.

It has long been recognized that certain types of growth whatever their situation in the body, respond better than others to radio-therapy, even though they may be situated in exactly the same part.

The soft proliferating mass is highly radio-sensitive whatever its histology. This kind of growth has an excellent blood supply, which is a great advantage in radio-therapy.

The hard infiltrating well-differentiated growth, extending deeply but slowly into the tissues in order to obtain enough blood supply to grow, is the least radiosensitive. There

is a third type of carcinoma which grows rapidly and is anaplastic. On account of its satisfactory blood supply it may form a fairly large non-ulcerating mass, or only partially ulcerated mass, near the os, and is associated with a huge mass in one or both broad ligaments. It is very radio-sensitive.

In the Royal Northern Hospital, Radiotherapy Department, the above principles guide the plan of treatment. Anything but a small growth receives preliminary X-ray therapy especially if it is not highly differentiated.

A proliferating mass is treated by a ring of radium in a rubber ring pessary-like container fixed mechanically to an intra-uterine tube. The growth fits into the ring and is evenly dosed.

An eroding cavity or stenosed vault is treated by a sphere fitting up in the vault and attached mechanically to an intra-uterine tube on a stem which passes through the sphere.

A large vault is utilized to take a large egg-shaped applicator comparable in size to Drs. Donaldson and Neary's model. I intend to use their principle of screening from now on.

Mr. Rees of the Gynaecological Department agrees with me that individualization has improved the results.

A new method of treating a mass in the broad ligament by rotation X-ray therapy focusing the X-rays accurately and offering more hope for these advanced cases is now being used at the hospital.

Mr. G. W. Blomfield: The Sheffield appliance for carcinoma of the cervix is for a single vaginal source of radium placed in the central axis. It is, perhaps, less effective in the cut off of radiation to the point generally known as "point A" but it is possibly more versatile and adaptable. It is used in conjunction with a separate uterine source and "spacers" of different sizes are used for packing the vaginal walls away from the appliance. This appliance has a spherical head of platinum giving 1 cm. screenage over the rectum reducing the dose in this direction to 25%. The main beams are directed upwards and forwards at angles which have been worked out after making a number of dissections on autopsies, the aim being to give maximal radiation to the parametrium and pelvic wall whilst not taking the rectum, bladder or pouch of Douglas above tolerance. A second applicator is now under construction, having a detachable cap which can be removed when there is difficulty in applying intra-uterine radium. This will then direct extra radiation upwards at an angle which can be adjusted to suit requirements. The vaginal radium is inserted after all else has been fixed to the satisfaction of the operator and can be removed without disturbing the appliance.

In answer to questions.—I do not think that the difficulty encountered in cases of stenosed vagina is of great moment. Those cases with advanced stenosing growth will not be cured by any technique we know of at present, whatever the type may be histologically. They require a modified technique.

The amount of radium used in the Sheffield appliance is 200 mg. of pure radium in a tube of active size 7 mm. length by 4.4 mm. diameter. The uterine source is 30 or 40 mg. total, in a separate uterine tube. The time of application is varied according to the size of the spacers used.

Previous trials, completed a year ago, with a lead appliance and two radon sources, have shown that the technique of using heavily screened radium in the central vaginal axis works clinically and makes increased dosage possible without danger, but the screenage must give adequate cut off of radiation in the correct anatomical directions.

Congenital Defects Following Rubella in Pregnancy.—IVOR HUGHES, F.R.C.S.

This case manifests most of the congenital lesions which have been stated by Gregg [1], Swan [2], Erickson [3] and other writers to occur when an expectant mother contracts rubella in the early months of pregnancy.

Mrs. E. contracted this disease in the second month of her first pregnancy, the infection being of a mild type. Her brother-in-law, who is a doctor, diagnosed the disease as rubella and insisted on her remaining in bed for three days although she stated that she felt well enough to carry on with normal duties. I stress this point because it has been suggested that the virulence of the unknown virus of rubella has possibly been enhanced in the war years, so producing lesions which have not been recognized earlier.

The baby was born two weeks after term (date of birth 21.11.40) and, like other cases quoted, he was small, ill-nourished and difficult to feed, pale, irritable and a poor sleeper. Weight at birth 6 lb. 6 oz.

Later a congenital cataract of the left eye was noted with enophthalmos. Nystagmus was demonstrated at a later date. This type of cataract bears no resemblance to any other type of congenital lesion of the eye described by Duke-Elder [6], Mason in 1937, Parsons in 1936 and others. Some observers note that a bilateral cataract is more common than a unilateral lesion.

Deafness was noticed as the child grew older and now deaf-mutism plus mental retardation are obvious.

He has the typical congenital heart lesion, due to a patent foramen ovale, in the inter-ventricular septum.

At present he is smaller and lighter in weight than the average child, and, in comparison with his brother, who is two years younger, appears to have microcephaly.

The boy has contracted no illness since birth which would be likely to cause any of these lesions.

The mother has had two children since the birth of this boy and both are healthy and normal in all respects. There is no familial history of any abnormality on either the maternal or paternal side.

In a survey of the literature Gregg [1] was the first to draw attention to these malformations, tracing examples back to late 1939. He recorded 78 cases but, in a small percentage of these, it was doubtful whether or not the mother suffered from rubella, and in one case mumps was thought to be the predisposing lesion.

Swan [2] and his co-workers of South Australia undertook a research for the National Health and Medical Research Council of Australia and examined 61 infants, 36 of which were found to have these congenital defects, and of these, 31 of the mothers had had an illness during pregnancy, usually in the first three months, which was thought to be rubella.

Later these observers published a further series of 10 cases in which all the mothers had suffered from rubella.

Reese [4] in America published 3 cases, Erickson [3] 11 cases, and Hope Simpson [5] in a letter to the *Lancet* described 2 cases—the only reference to the subject in this country.

In Erickson's paper in the *American Journal of Pediatrics* he states that in Gregg's series of 78 cases of congenital cataract, 44 of them had congenital heart disease also and, secondly, in his reference to Swan's papers, in which there were a total of 49 cases, 25 of the mothers developed rubella in early pregnancy and the 25 babies all had congenital defects; of those developing the disease in the third month only 50% had defects, and, after the third month, only two out of 16 of the babies manifested abnormalities.

Finally he states that in the second series published by Swan and in his own 11 cases, 100% of the offspring showed congenital lesions.

The pathology causing the abnormalities is obscure but it has been suggested that as the filtrable virus of rubella passes through the barrier of the chorionic villi at a time when lens and septa formations are occurring (i.e. sixth to eighth week of pregnancy) eye and vascular lesions are the sequelæ. Therefore the percentage of congenital lesions must be higher if the disease is contracted in the first three months of pregnancy.

Two of the writers (Erickson and Reese) suggest that, as these lesions follow rubella, it might be justifiable to terminate the pregnancy in cases where the disease has been proven. Such a course, in my opinion, could not be adopted at the present time. So far only positive evidence that rubella causes congenital lesions has been published—in other words the writers have traced back the history of rubella in cases showing the lesions. I feel that an investigation covering a large number of antenatal cases should be undertaken in order to try and discover the percentage of cases of maternal rubella in pregnancy in which no congenital lesions were subsequently manifested.

It is only by collecting both positive and negative findings that one can assess the correct method of dealing with such cases, and in order to facilitate the tracing of cases of rubella the disease should be made notifiable throughout the country.

Notes on Certain Trends in Public Health Work in the City of New York and in the States of New York, Massachusetts and Georgia

By MELVILLE D. MACKENZIE, M.D.

Senior Medical Officer, Ministry of Health

It is impossible to visit the United States without being struck with the energy and enthusiasm with which the medical officers and nurses of the public health departments approach their work, particularly in relation to such problems as poliomyelitis, cancer, venereal diseases, home accidents and health education.

Fortunately, at the present time, the United States are in a position to back this zeal adequately, both financially and in trained personnel. Consequently great progress has been made in social medicine in America at a time when our own effort has been unavoidably limited by the war to the solution of questions less directly concerned with ordinary public health problems.

The time at my disposal only permitted me to visit the City of New York and three States. Consequently my notes are based on observations made in relation to these four areas only. No attempt was, of course, made to compare any results achieved in America with those realized in this country, but rather I studied the latest trends and methods of administration in relation to social medicine with special reference to the control of communicable diseases.

Taking first the general public health administration of the Regions I visited, the following points emerge as of particular interest.

State Health Administration.—The Health Commissioner of a City or State is not responsible to any lay representative or other committee for his expenditure but only directly to the State Governor or, in New York City, to the Mayor.

He is, however, generally associated with some form of Board of Health or Advisory Council, the constitution, powers and activities of which vary considerably in the different States. In the City of New York the Board of Health consists entirely of physicians most of whom are professors in one or other of the universities. This Board advises the health commissioner and, in addition, has comprehensive legal powers in connexion with the establishment of the sanitary code for the City and in dealing with individuals who break it. The sanitary code which is entirely prepared by this body has full legal force, with the proviso that none of its enactments are in contradiction to any of the State or Federal laws.

In some States Boards of Health recommend the health officer for appointment and have considerable legislative powers. In others the Board may be purely advisory and consist entirely of medical experts or of a majority of medical experts with a number of laymen. In other cases an advisory council may exist largely as a means of interpreting the health officer's programme to the general public and in this case is constituted by members representative of the leading social organizations of the area and individuals particularly interested in public health.

The care with which the amount of work done, the results achieved and the annual expenditure involved are estimated is a striking feature of all branches of the health work. Elaborate systems are devised and used for determining this and, moreover, through the use of health practice indices the results in any one locality are constantly compared with those in neighbouring localities and in relation both to the individual State and the United States as a whole.

The closest liaison is maintained between the staff of the health department and the universities. Members of a university staff are extensively used on a part-time basis by the health authority and conversely members of the health department staff are utilized as lecturers in their speciality in the faculties of medicine.

Clinics in general are run largely by part-time physicians who have been selected for the purpose and given special training at the cost of the health department. Such part-time doctors are given a detailed handbook covering the administrative aspects of their work and are supervised by a number of whole-time consultants who visit the various clinics and control the work generally. A medical officer of the health department is, of course, in charge of each branch of the work from the purely administrative angle.

It is interesting to note that in clinics generally, including those for tuberculosis, venereal disease and maternity and child welfare, every patient is given a card with an appointment for a definite time so that waiting is obviated.

First-class laboratory facilities are available for the use of practitioners. These are regarded not only as of great value to practitioners from the point of view of diagnosis but also as an important factor in winning the co-operation of practising physicians in carrying out the State health programme.

Much stress is laid on vital statistics and a strong statistical division is regarded as an essential part of every health body. Detailed statistical data are regularly used not only for assessing results in each branch of a health department's work but also as an aid to planning the future programme, particularly as regards the relative practical importance of the various branches of work as claimants on the budget allocation.

In the United States generally it is remarkable what powers are available in connexion with the notification and compulsory treatment of such diseases as those of the venereal group, tuberculosis, &c. Indeed many of the sanitary codes make it a crime to spread any communicable disease and this is very broadly interpreted.

The closest co-operation is invariably maintained with all practising physicians and the view is widely held amongst health officers that types of clinical activity which are intended to promote the health of the individual should be allocated to practising physicians as soon as they are willing and ready to undertake this work. Health officers make every effort to win the confidence, friendship and approval of the organized medical body of each community, and local medical societies are urged to set up a special public health committee which aids and advises the health officer in his programme and interprets his policies and activities to the local medical profession. Health officers are encouraged to become members of the local medical society and to take an active part in the affairs of that organization. The membership of the Board of Health wherever possible includes one or more representative public-spirited practitioners who assist the health officer in working out a co-operative programme.

CONTROL OF COMMUNICABLE DISEASES

Importance is attached in the United States to notification of communicable diseases as a *method of estimating the size of a problem* even if prevention or other public health activity is not directly or at the moment possible. In the State of New York which may be taken as an example, some 33 diseases are notifiable, including cancer.

It is very interesting to note that the striking reduction in the diphtheria, scarlet fever, typhoid and measles death-rates has resulted in a deliberate transfer of effort from these diseases to such other killing conditions as cancer, accidents and heart disease.

Every care is taken to ensure that epidemiologists are in constant touch with clinical cases and that some of their time is regularly spent in the wards of a hospital taking cases of communicable diseases. The epidemiologists attached to the health department act as a consulting service to practitioners and also see all doubtful cases on behalf of the health department. Their duties are concerned only with the diagnosis of the case and a public health nurse is responsible for seeing how far quarantine measures are possible in the home or are being carried out.

Extensive use is made of expert advisory committees in connexion with the control of communicable diseases generally. These experts are not members of the staff of the health department but sit in an advisory capacity only, particularly in connexion with outbreaks of unusual diseases.

Stress is laid on the maintenance of close co-operation with practitioners in the control of communicable diseases through the medium of regular letters and circulars outlining the epidemiological importance of any outbreak which has occurred and describing the facilities which are available in the health department for the use of practitioners. Similarly, when a case of infectious disease is notified a special leaflet is sent to the parent outlining the cause of the disease, the method of its spread, and describing the help that can be given by the health department.

Placarding for infectious diseases was for a time tried in New York City but is not now regarded as being of practical value. The general view is that in actual practice very little if anything is achieved by placarding and for its execution a disproportionate amount of the time of the public health staff is required.

A check is kept on notifications through the medium of the official and private laboratories. The official laboratories notify the health department of all positive specimens examined and private laboratories are only licensed on condition that this information is also supplied to the health department. In cases where no notification has been received directly from the practitioner the question is taken up with him.

The view held both in New York City and New York State with regard to infectious diseases generally is that these can be perfectly safely nursed in the wards of an ordinary general hospital, provided proper precautions are taken. All post-war hospital planning, in the case of the City of New York for example, is based on the incorporation of infectious disease sections, including tuberculosis, as parts of general hospitals.

Measles.—With regard to measles, a large amount of work is being done both experimentally and in the field in connexion with the use of gamma globulin and placental globulin. In recent work by the Department of Health of New York City gamma globulin (2 c.c.) was administered to 814 household contacts (aged 6 months to 6 years) of measles. None developed regular measles, 78.7% were completely protected, and 21.3% had modified measles. Of this latter group 92% had mild and 8% had moderate measles. In a group of 65 similar contacts receiving no prophylaxis 83% developed measles. As a result of these and other observations in New York City gamma globulin is to be distributed for children under five who are contacts to measles, particularly for use in hospital wards where a case of measles occurs.

Plague.—During my visit I was very interested to see the detailed rat proofing of the buildings at the La Guardia aerodrome at New York. This, I believe, is one of the first aerodromes to be completely rat-proofed. The importance of this in connexion with aerodromes is illustrated by the fact that on two occasions rats have arrived alive in the airport of La Guardia, transported by aeroplane. In one case a litter of rats was actually born on an aeroplane during flight.

Scarlet fever.—Decreasing importance is attached to scarlet fever as an entity and it is generally regarded as one of a group of hæmolytic streptococcal infections, including septic sore throat. Thus in New York City the reportable disease "Scarlet Fever" is now officially included in a wider classification, namely "Streptococcal Sore Throat, including Scarlet Fever". Contacts are not excluded from school or work. Visits by nurses to the homes of cases of scarlet fever are no longer required and children recovered from streptococcal sore throat, including scarlet fever, may be readmitted to school on a card issued by the health department or by a physician.

Smallpox.—With regard to smallpox, no child is admitted to school unless successfully vaccinated.

Tetanus.—In the opinion of the health authorities, the amount of tetanus in certain areas is such as to render it desirable for all children to be immunized against this disease early in life. A considerable amount of work is going forward in the preparation of a tetanus, diphtheria and whooping cough prophylactic for use amongst young children. Consideration is also being given to the desirability of protecting pregnant women against tetanus as a routine measure in some areas.

Typhoid.—The typhoid incidence rate was very low in the regions visited and this is attributed to the satisfactory water supplies, the pasteurization of milk and the close supervision of food handlers. Great importance is attached to carriers, and in the City of New York, for instance, chronic typhoid "carriers" must comply with the following requirements:

- (a) Submit specimens as often as may be required.
- (b) Report in person or by writing each month to the department of health.
- (c) Abstain from handling food, drink or dishes, nursing the sick or caring for children.

(d) Notify the health department of any change of address or place of employment; such change or occupation to be conditional on the consent of the health department.

A "carrier" remains under the direct supervision of the department of health indefinitely unless (1) the gall-bladder has been removed and satisfactory tests carried out subsequently or (2) five consecutive stool specimens taken not less than one year apart are reported as containing no typhoid bacilli. "Carriers" are in practice kept under very close supervision and are regularly visited either by a nurse or a doctor. The health departments are commonly in a position to pay up to £12 a month from health department funds in a case where the "carrier" has to change his occupation. Generally speaking operative treatment is not recommended but if a patient insists a health department will make a grant of up to £50 for the operation.

Rheumatic fever.—Rheumatic fever in the United States is regarded as one of the foremost health problems of childhood.

The object aimed at is to lessen the chances of developing the disease, to do all possible to prevent heart damage once the disease has occurred, to prevent recurrence of the infection following the initial attack, to prevent mental and emotional maladjustment in the patient and members of his family, and, perhaps most important of all, to prevent the labelling as "a cardiac cripple" of a child who has satisfactorily recovered or been erroneously diagnosed. Great stress is laid on the importance of case-finding. This is done chiefly by practitioners but also through public health nurses, school nurses and teachers, child health conferences, crippled children's clinics, social agencies and parents.

In a rheumatic fever programme a paediatrician is employed on a part-time or full-time basis and is responsible for the medical care of all children with rheumatic fever in each stage of treatment whether in a clinic, hospital, convalescent home, foster home or the child's own home. In this way continuity of medical care is assured. A medico-social consultant is responsible for seeing that any family and environmental difficulty, or the feelings of the child about his condition, do not prevent him from following the treatment recommended or getting the maximum benefits from this treatment. Finally, a public health nursing consultant is responsible for supervising the nursing services for children under the programme. Diagnostic services are provided by the paediatrician in clinics with all necessary facilities, including fluoroscopic and electrocardiographic machines. Consultative services are made available to private physicians, school physicians and county health officers.

When a child has recovered from his rheumatic infection he is encouraged to live as normal a life as possible. At the same time every effort is made to prevent a recurrence of the infection and he returns to the State rheumatic clinic periodically for medical examination and advice. Finally, great stress is laid on the education of doctors and the public both in relation to the disease itself and to the rheumatic fever programme.

A large amount of work is being done at the present time in connexion with the prophylactic use of the sulpha drugs in respect of rheumatism but the question can still only be regarded as in an experimental stage.

Tuberculosis.—Broadly speaking the methods used in the control of tuberculosis in the States I visited corresponded with those used in the progressive areas in this country. There are, however, a number of special points in American practice to which attention should be drawn.

Tuberculosis work generally is done in the closest possible association with general practitioners, and in New York City, for example, any alteration in the tuberculosis code is only made in consultation with practitioners.

All forms of tuberculosis are notifiable. In addition, in some regions, cases of tuberculosis may be removed to hospital by the health department if the continued residence of the patient in the place where he may be is considered dangerous, or likely to be dangerous to the lives and health of other persons. The patient may be compulsorily retained in hospital until the health department is satisfied that he may return to his home without risk of spreading the disease.

The clinics are in general staffed by part-time physicians, on a sessional basis, who have been specially selected and have had a basic training in tuberculosis. In the City of New York, for example, the work is carried out by 85 such part-time physicians. These doctors are required to work in accordance with a manual of administrative procedure setting out the diagnostic standards and the classification of the different stages of the disease but the clinical side of the work is left to their individual initiative.

Commercial firms are commonly employed for mass radiography which is done under contract.

"Contact" examination is along the lines generally followed in the United Kingdom, certain age-groups attending regularly over a prolonged period and others only being examined once. Importance is attached rather to the number of households infected with tuberculosis than to the number of cases.

Mass radiography is being used on a steadily increasing scale amongst industrial groups and others. The work is, broadly speaking, limited to various groups rather than extended to the whole population.

School teachers are regularly X-rayed as well as all nurses.

There is an increasing tendency to regard the sanatorium as the administrative centre of the tuberculosis service in its area, thus combining preventive and curative work. This

is well illustrated in the case of the Middlesex Sanatorium in Massachusetts. The institution, which is modern in construction, deals with in-patients, out-patients, and "contacts" in the clinics in the surrounding area. The staff of the sanatorium, both doctors and nurses, consequently spend a part of their time in the sanatorium wards and the rest in work in the clinics, including the treatment of ambulant cases, the search for new cases and the observation of "contacts". All the clinic card indexes are kept at the sanatorium. In addition members of the staff act as consultants to practitioners and also undertake a considerable amount of lecturing to local medical societies and other educational work.

The greatest importance is attached to health education work amongst both the local practitioners and the public generally.

All services, including in-patient treatment at a sanatorium like the Middlesex, are entirely free and the technical standards reached have such a high reputation that all classes of the population, including the richest, do not hesitate to avail themselves of free treatment.

Veneral diseases.—With regard to the control of venereal disease generally in the United States the following points are of interest:

(1) The very great energy and large expenditure of money that are being put into the central and local programmes for the control of these diseases.

(2) Venereal diseases in New York City and the States I visited were not only notifiable but treatment was compulsory. Reports on every venereal disease specimen examined and found positive are sent by all laboratories, including private laboratories, to the health department concerned and it is claimed in New York City, for example, that between 90 and 95% of new infections with syphilis are brought to the attention of the health department either through notification by doctors or the laboratories.

(3) In addition to special venereal disease legislation, action is frequently taken under a general clause which exists in many sanitary codes making it a crime to spread any communicable disease. Patients are regarded as free from infection only after a specific treatment with a definite number of injections laid down by the Academy of Medicine has been completed; no notice is taken of the serum reaction for the purpose of determining freedom from infection in the case of syphilis.

(4) The basic problem in the control of venereal disease is considered to be education and very great efforts are made to bring the necessary information to the notice not only of the laity but of all practitioners.

Among the facilities offered free to the general practitioner by the health department are laboratory examinations, lumbar puncture, clinical consultative service, provision of anti-syphilitic drugs, epidemiological service in connexion with contacts and post-graduate instruction.

A beginning has been made of teaching facts about venereal disease both in coloured and white schools. The instruction is given in biology classes and, in the case of coloured children in some areas, begins at the age of 14 and with the white children a year or so later. A considerable amount of experimental work in this connexion has already been done and the work is being expanded.

(5) There is a feeling that in the past in clinics in the United States, too much energy has been devoted to the long-continued treatment of non-infectious persons, who may constitute 85% of those attending the venereal disease clinics. At the present time, efforts are being concentrated largely on the search for cases, the examination of "contacts" and the treatment of patients so as to render them non-infectious as rapidly as possible. When a doctor has notified a case he is asked by the health department whether he desires to treat the case himself and whether he is willing to ascertain the names of the contacts. If he declines the former the case is compulsorily treated in a clinic until it is free from infection. If the doctor does not wish to trace the contacts, this work is done by a public health nurse. It is interesting to note that men are commonly employed to follow up male contacts.

(6) Both pre-marital and pre-natal examinations are compulsory in many States. In some States blood examination is also required in the case of workers in industry. If an individual is found to require treatment he is allowed to continue his work conditional on completing a prescribed course of treatment. Some commercial companies insist on the whole staff from the President of the Board downwards undergoing regular blood examinations.

Widespread blood examinations are being pushed by the Chambers of Commerce with a view to preventing physical and mental disabilities which might interfere with a man's work and also in order to avoid possible compensation claims. The results of these sera examinations are interesting. Thus 399,218 individuals were examined by

Rheumatic fever.—Rheumatic fever in the United States is regarded as one of the foremost health problems of childhood.

The object aimed at is to lessen the chances of developing the disease, to do all possible to prevent heart damage once the disease has occurred, to prevent recurrence of the infection following the initial attack, to prevent mental and emotional maladjustment in the patient and members of his family, and, perhaps most important of all, to prevent the labelling as "a cardiac cripple" of a child who has satisfactorily recovered or been erroneously diagnosed. Great stress is laid on the importance of case-finding. This is done chiefly by practitioners but also through public health nurses, school nurses and teachers, child health conferences, crippled children's clinics, social agencies and parents.

In a rheumatic fever programme a paediatrician is employed on a part-time or full-time basis and is responsible for the medical care of all children with rheumatic fever in each stage of treatment whether in a clinic, hospital, convalescent home, foster home or the child's own home. In this way continuity of medical care is assured. A medico-social consultant is responsible for seeing that any family and environmental difficulty, or the feelings of the child about his condition, do not prevent him from following the treatment recommended or getting the maximum benefits from this treatment. Finally, a public health nursing consultant is responsible for supervising the nursing services for children under the programme. Diagnostic services are provided by the paediatrician in clinics with all necessary facilities, including fluoroscopic and electrocardiographic machines. Consultative services are made available to private physicians, school physicians and county health officers.

When a child has recovered from his rheumatic infection he is encouraged to live as normal a life as possible. At the same time every effort is made to prevent a recurrence of the infection and he returns to the State rheumatic clinic periodically for medical examination and advice. Finally, great stress is laid on the education of doctors and the public both in relation to the disease itself and to the rheumatic fever programme.

A large amount of work is being done at the present time in connexion with the prophylactic use of the sulpha drugs in respect of rheumatism but the question can still only be regarded as in an experimental stage.

Tuberculosis.—Broadly speaking the methods used in the control of tuberculosis in the States I visited corresponded with those used in the progressive areas in this country. There are, however, a number of special points in American practice to which attention should be drawn.

Tuberculosis work generally is done in the closest possible association with general practitioners, and in New York City, for example, any alteration in the tuberculosis code is only made in consultation with practitioners.

All forms of tuberculosis are notifiable. In addition, in some regions, cases of tuberculosis may be removed to hospital by the health department if the continued residence of the patient in the place where he may be is considered dangerous, or likely to be dangerous to the lives and health of other persons. The patient may be compulsorily retained in hospital until the health department is satisfied that he may return to his home without risk of spreading the disease.

The clinics are in general staffed by part-time physicians, on a sessional basis, who have been specially selected and have had a basic training in tuberculosis. In the City of New York, for example, the work is carried out by 85 such part-time physicians. These doctors are required to work in accordance with a manual of administrative procedure setting out the diagnostic standards and the classification of the different stages of the disease but the clinical side of the work is left to their individual initiative.

Commercial firms are commonly employed for mass radiography which is done under contract.

"Contact" examination is along the lines generally followed in the United Kingdom, certain age-groups attending regularly over a prolonged period and others only being examined once. Importance is attached rather to the number of households infected with tuberculosis than to the number of cases.

Mass radiography is being used on a steadily increasing scale amongst industrial groups and others. The work is, broadly speaking, limited to various groups rather than extended to the whole population.

School teachers are regularly X-rayed as well as all nurses.

There is an increasing tendency to regard the sanatorium as the administrative centre of the tuberculosis service in its area, thus combining preventive and curative work. This

is well illustrated in the case of the Middlesex Sanatorium in Massachusetts. The institution, which is modern in construction, deals with in-patients, out-patients, and "contacts" in the clinics in the surrounding area. The staff of the sanatorium, both doctors and nurses, consequently spend a part of their time in the sanatorium wards and the rest in work in the clinics, including the treatment of ambulant cases, the search for new cases and the observation of "contacts". All the clinic card indexes are kept at the sanatorium. In addition members of the staff act as consultants to practitioners and also undertake a considerable amount of lecturing to local medical societies and other educational work.

The greatest importance is attached to health education work amongst both the local practitioners and the public generally.

All services, including in-patient treatment at a sanatorium like the Middlesex, are entirely free and the technical standards reached have such a high reputation that all classes of the population, including the richest, do not hesitate to avail themselves of free treatment.

Veneral diseases.—With regard to the control of venereal disease generally in the United States the following points are of interest:

(1) The very great energy and large expenditure of money that are being put into the central and local programmes for the control of these diseases.

(2) Venereal diseases in New York City and the States I visited were not only notifiable but treatment was compulsory. Reports on every venereal disease specimen examined and found positive are sent by all laboratories, including private laboratories, to the health department concerned and it is claimed in New York City, for example, that between 90 and 95% of new infections with syphilis are brought to the attention of the health department either through notification by doctors or the laboratories.

(3) In addition to special venereal disease legislation, action is frequently taken under a general clause which exists in many sanitary codes making it a crime to spread any communicable disease. Patients are regarded as free from infection only after a specific treatment with a definite number of injections laid down by the Academy of Medicine has been completed; no notice is taken of the serum reaction for the purpose of determining freedom from infection in the case of syphilis.

(4) The basic problem in the control of venereal disease is considered to be education and very great efforts are made to bring the necessary information to the notice not only of the laity but of all practitioners.

Among the facilities offered free to the general practitioner by the health department are laboratory examinations, lumbar puncture, clinical consultative service, provision of anti-syphilitic drugs, epidemiological service in connexion with contacts and post-graduate instruction.

A beginning has been made of teaching facts about venereal disease both in coloured and white schools. The instruction is given in biology classes and, in the case of coloured children in some areas, begins at the age of 14 and with the white children a year or so later. A considerable amount of experimental work in this connexion has already been done and the work is being expanded.

(5) There is a feeling that in the past in clinics in the United States, too much energy has been devoted to the long-continued treatment of non-infectious persons, who may constitute 85% of those attending the venereal disease clinics. At the present time, efforts are being concentrated largely on the search for cases, the examination of "contacts" and the treatment of patients so as to render them non-infectious as rapidly as possible. When a doctor has notified a case he is asked by the health department whether he desires to treat the case himself and whether he is willing to ascertain the names of the contacts. If he declines the former the case is compulsorily treated in a clinic until it is free from infection. If the doctor does not wish to trace the contacts, this work is done by a public health nurse. It is interesting to note that men are commonly employed to follow up male contacts.

(6) Both pre-marital and pre-natal examinations are compulsory in many States. In some States blood examination is also required in the case of workers in industry. If an individual is found to require treatment he is allowed to continue his work conditional on completing a prescribed course of treatment. Some commercial companies insist on the whole staff from the President of the Board downwards undergoing regular blood examinations.

Widespread blood examinations are being pushed by the Chambers of Commerce with a view to preventing physical and mental disabilities which might interfere with a man's work and also in order to avoid possible compensation claims. The results of these sera examinations are interesting. Thus 399,218 individuals were examined by

the laboratories of New York State during one year. By this means 7,659 individuals or 1.9% of the total were found to be positive.

With regard to pre-marital examinations, from a random sample number of 2,887 in New York State 1.2% males and 1.3% in females gave positive serological reactions.

Examination of restaurant workers is optional in some areas but compulsory in others. (7) A considerable amount of work has been done in connexion with the provision of prophylactic facilities but in the civilian population these have been found to be hardly ever used and are not considered to be of practical application from an administrative point of view.

Cancer.—The ideal aimed at is "the prevention of 50% or more of the hundred thousand deaths from cancer which are occurring annually in the United States". The great expenditure of both energy and money in the cancer control programmes has already given very striking results. These are shown by the following figures in the two areas studied.

In the State-aided clinics of Massachusetts the shortening of the time between a patient first noticing symptoms of the disease and presenting himself to a physician has been used as one measure of the effectiveness of the cancer programme. In the early years of the programme this delay averaged 6.5 months. Between 1936 and 1939 it was 5.3 months and in 1940 4.6 months. Since this date a further fall has occurred bringing the time down to 3.2 months, or *half that of earlier years*.

The second period of delay is that between first consulting a physician and visiting a cancer clinic. This delay has been decreasing rapidly and is *now about half what it was in the early years of the clinics*.

The third delay is between presentation at a clinic and the beginning of treatment. At the present time about *two-thirds of the patients are treated within one week and over 90% within one month of the first clinic visit*.

In the State of Georgia the effect of the cancer control programme is shown by the considerable increase of patients presenting themselves at cancer clinics who are found not to be suffering from the disease. Thus in the year 1937, 81.2% of all the cases presenting themselves at State-aided clinics were malignant, whilst, in 1942 only 59.5% were malignant. This percentage has continued to fall steadily but the corrected figures for later years are not yet available.

Briefly the programmes which have resulted in these striking results are based on: (1) Early recognition. (2) Notification. (3) Provision for free and early treatment. (4) Search for new cases and "follow-up" work. (5) Intensive education of physicians, public health nurses and the laity, including instruction in the higher classes of schools. (6) Research.

Home and farm accidents.—Great energy is being displayed in America in the prevention of accidents in the home and on the farm. In considering deaths for all causes and for all age-groups in the United States it will be found that accidental fatalities of all types are third in numerical importance. For the country as a whole in 1941 there were more deaths from accidents in the home than motor vehicle deaths (30,000 as compared with 28,200) and nearly twice as many as from industry or public deaths due to causes other than motor vehicles. In 1942 in New York City accidents were the principal cause of death of all children from 1 to 14 years and in the age-group 5 to 9 years deaths due to accidents are almost as great as the deaths from all diseases put together.

As an example of the importance attached to this work mention may be made of the organization set up by the Health Department of the State of New York which works along the following lines and which may be regarded as typical.

A Home and Farm Safety Advisory Committee has been set up by the Division of Public Health Education.

It works through a number of sub-committees covering research and statistics, legislation, household safety, personal health and safety, finance, farm safety, safety in housing and safety to children in farm work. Technical brochures are sent to all architects and engineers regarding safety of construction in houses. A similar booklet exists with regard to electrical fittings in which stress is specially laid on the importance of plugs being at a height inaccessible to children, safe wiring, and the avoidance of shock hazards in washing machines, electrical toys, &c.

A circular is sent to every practitioner inasmuch as "preventive medicine is definitely a part of a physician's practice and the prevention of accidents, especially in the home, is an important part of his work". A committee of physicians on personal health and safety has been set up which amongst other activities draws the attention of medical practitioners to such physical conditions as may cause accidents in the home, i.e. defective eyesight, impaired hearing, muscular inco-ordination, dizzy spells, night blindness, crippled conditions, epilepsy, &c.

Perhaps the most important work is done by the public health nurses who work in accordance with the "Home Safety Manual for Public Health Nurses". This is an excellent document explaining in detail the causes of accidents in the home. These may be due to:—first, faulty design of the house (faulty construction of stairs, improperly lighted steps, insufficient overhead clearance on stairways, faulty construction of stair rails, insufficient light, disorder, faulty planning of kitchen space, too few exits, doorways too near steps); secondly, neglect of maintenance (defective stair covering, ice on steps, slippery

cracked linoleum, insecure screen fastenings, loose plaster, broken chair rungs, &c.); thirdly, faults in electrical maintenance (using electrical appliances in damp location, overloaded circuit, frayed cords, using fuses of too great capacity, faulty washing machines, over-heating of electric irons, over-turning of electric heaters, unprotected whirling plates of electric fans, &c.); fourthly, lack of skill (floor left slippery after waxing, using substitutes for ladder in curtain hanging, mis-use of knives, cooking steam, bursting of canning jars, botulism in food preservation, improper position in heavy lifting, explosion during dry-cleaning, leaking gas). The booklet also deals with the danger to children of suffocation, choking, burns and scalds and also stresses the importance of the protection of the aged against accidents so as to obviate their becoming a burden on the rest of the family. In the case of the aged attention is particularly drawn to the avoidance of falls (slippery walks, stairs without handrail, slippery bath tubs, poorly lighted stairways, high beds, defective sight). The public health nurses systematically visit houses drawing attention to defects which may be the cause of accidents and, at the same time, distribute to householders popular booklets on the importance of accidents in the home and their prevention. In addition to wireless talks and other means of publicity much educational work is done through the medium of the schools, especially through the Junior Safety Voluntary Movement.

PUBLIC HEALTH NURSES

The work of the public health nurses is amongst the most interesting features of the health work in the United States.

Although her visit usually originates in connexion with a case of sickness, the whole approach of the nurse is *to the family rather than to the individual*. In addition to giving nursing attention to the patient the nurse invariably takes the opportunity of dealing with other health problems in the home such as cleanliness of the house and the children, their food, clothing and sleeping habits, as well as defects in the house itself. She also explains where any medical facilities that the family may require are available and gives information on such points as periodic health examination, immunizations, accident prevention and the prevention and recognition of early symptoms of such diseases as diabetes, cancer, orthopaedic defects, rheumatic fever, tuberculosis and syphilis. Since the health of one member of the family may affect directly or indirectly all the others, the public health nurse considers primarily what help can be given from a family point of view.

HEALTH EDUCATION

In the United States very high priority in public health work is invariably given to health education, including that of practising physicians and the laity as well as to regular in-service training of public health officers. It is held that "no public health programme can be completely successful in the United States without the confidence and support of the people who benefit by it".

The public health education of the practitioner forms to an increasing degree an important part in the curriculum of the medical schools, and, after qualification, widely varying courses of post-graduate study are available. Handbooks on certain specified diseases are sent to every practitioner by health departments, e.g. manuals on cancer, venereal disease, &c., as well as a brochure outlining briefly what the work of the health department is and stressing particularly the ways in which the department may be of assistance to him and how to avail himself of this help.

The greatest attention is paid to the in-service training of the staff of the health department. After or before appointment doctors, nurses and sanitary personnel are sent for special courses at a university and are also given intensive training in the activities of the health department itself before taking up their work. During their time of service, study leave is given to technical members of the staff of the health department and through the payments of expenses, &c., the staffs are encouraged to attend National and Inter-State conferences.

Health education of the laity may be divided into that done in the schools and that done amongst the adult population. The health department works in the closest association with the education department, often with a joint committee. The health syllabus for school teaching is exceedingly comprehensive and covers all grades. It is interesting to note that a beginning is being made in the teaching of certain aspects of cancer and venereal disease in schools. One method of health education which is extensively used is to give children written questions and ask them to consult their parents with regard to the answers, thus carrying health education into the home itself through the school.

In the case of adults every possible method of publicity is utilized and the relative values of the different methods employed are constantly assessed. The health education department in a City or State forms a separate division of the health department. In New York State for example the division of health education has a director and two assistant directors with the following sections:

Publications (sub-sections for medical editing, representation of staff, bulletin, illustrating and distributing, designing of posters and general art work, charts and graphs).

Information Service (health education institutes, public addresses, field health education, local and general health programmes).

News releases (sub-sections for local publication, feature articles, cartoons, press photographs).

Radio and recordings (electrical transcriptions of original radio plays, weekly programme from 25 radio stations).

Photographic service (production of policy and technical sound and silent motion pictures, film strips).

Visual instruction (distribution of films and exhibits, projection and handling of exhibits).

Health mobile service (motion picture projection at health meetings).

The staff of the department includes artists, film producers, journalists, playwrights, &c., and includes photographic and other requisite machinery for the production of health films of all kinds.

Another method of publicity in connexion with health education is to set up small exhibits and posters which are constantly changed in the out-patient departments of hospitals. Such exhibits may deal with clothing for children, purity of milk and food supplies, cooking, &c. It is felt that patients who are waiting to see a doctor are likely to be more receptive to health education than those who are in good health.

Radio and films are two methods widely used. Radio plays and regular talks are broadcast and "spot announcements" in the form of short health messages are frequently interspersed in radio programmes, particularly at peak listening hours.

In the case of films fifteen-minute short flashes dealing with health are interspersed in the ordinary commercial programmes. The film service of the New York City Health Department lends films free, together with the necessary projecting equipment and operators for day-time and evening showing in schools, health centres, churches, factories, &c. The growing popularity of this service is attested by the fact that some 200 programmes were scheduled each month during the past year reaching a total of nearly 2,000 individual showings for the full twelve-months period. Correspondence from the general public is utilized both as a measure of the value of health education and also as a means of conveying information. Thus the New York City Health Department during 1944 received on an average 800 telephone inquiries a month. In addition, 30,000 letters were received during the same year asking for advice on health. Every telephone inquiry, letter or call was answered individually.

The news releases by the health department are on the same scale and during 1944 in New York City of the 42 news releases from the health department one or more was used by 391 newspapers in the city and constituted the basis for 1,825 items.

FOOD CONTROL

A visitor to the United States cannot fail to be struck by the cleanliness with which food is prepared and served even in the case of inexpensive restaurants. Apart from the very careful supervision exercised over purity of food products, the health department closely supervises hotels, restaurants and bars from the point of view of cleanliness in cooking and serving.

Bacteriological swabs are regularly taken by inspectors of the health department from utensils including glasses on the serving tables of restaurants and cafés and the average plate count per utensil-surface examined must not exceed 100. Higher counts are presumptive evidence of inadequate cleansing or recontamination by handling or during storage and are consequently a breach of the sanitary code and dealt with accordingly.

Restaurant keepers must supply their employees with at least one clean overall daily both in the service rooms and in the kitchens.

Milk may only be served to customers from sealed bottles opened by the customer himself.

It has been exceedingly difficult to summarize the information I gathered in the time available. Fortunately, I was able to collect a very comprehensive documentation of some 300 books, publications, and pamphlets, covering in detail the various points I have referred to. This documentation is in my office at the Ministry of Health, and I shall be most happy to make the relevant sections available to any member interested in any particular problem or desirous of giving consideration to the possibility of applying it in his own work.

In conclusion I sincerely hope that as soon as ever circumstances permit it may be possible for many of my colleagues to go to the United States and avail themselves of the invariable kindness and generosity of the Americans in putting at our disposal full information regarding their technical progress and administrative experience.

Section of Urology

President—F. MCG. LOUGHNANE, F.R.C.S.

[June 28, 1945]

Some Surgical Aspects of Urinary Bilharziasis

By R. OGIER WARD, M.Ch., F.R.C.S.

BILHARZIASIS is a disease which produces many important changes in the urinary tract and is, if only for that reason, worthy of the interest of urologists. The main object in this paper is to direct attention to the fact that patients with the symptoms of this disease, typical or obscure, may be expected to make their appearance in the hospitals of this country during the years which lie immediately ahead of us, for British troops have served in countries where bilharziasis is ever present, and many have undoubtedly been infected with it. Napoleon's troops who served in his march to the Pyramids suffered from hæmaturia, which was undoubtedly of bilharzial origin. In "Notice sur l'hématurie qu'éprouvent les Européens dans la haute Egypte et la Nubie" A. J. Renoult, médecin, chirurgien, majeur de la gendarmerie d'élite, has something to say on this subject. His paper was read at a meeting "en messidor, an onze" and was published in the *Journal Général de Médecine, de Chirurgie et de Pharmacie* in 1803. Renoult says: "Elle parut affecter plus particulièrement les cavaliers, n'épargne même pas les chevaux; ses ravages se portèrent principalement sur les plus jeunes." He believed that it was caused by excessive sweating, forced marches, and riding horses "vifs et fougueux".

The cavalry were probably more affected than the infantry because they were exposed thrice daily to the risk of infection when watering their horses. I may remark that as a gunner officer in the Suez Canal Zone in 1915 such waterings were my almost daily duty, and I remember the strict orders prevailing against anyone getting into the branch of the so-called Sweet Water Canal allotted to us. I would like to add that I am certain—for I was already a budding urologist—that none of our horses suffered from hæmaturia. Renoult's observations that the younger soldiers were chiefly affected is probably to be explained by the fact that the old soldiers with twinges of rheumatism in their back muscles are but little thrilled by the opportunity of a bathe. Renoult noticed "les urines rares, épaisses et irritantes", also that "leur âcreté doit se faire particulièrement sentir sur les veines qui rampent le long des parois internes de la vessie". He treated his patients with abundant drinks but he sadly remarks that: "mais chez un aussi grand nombre l'hématurie est devenue si rebelle qu'elle ne leur laisse que la triste perspective d'une vieillesse toujours souffrante." During the South African War 625 cases became infected and a few were met with amongst soldiers returning to England. In 1911, 359 men were still drawing pensions amounting to £6,400 per annum, whilst there were others who had already been permanently pensioned on account of the disease. In the war of 1914-1918 there were more cases, and in 1915 a Commission under Professor R. T. Leiper had been sent to Egypt to study bilharziasis, and later published a valuable report and proved the correct method of its transmission. A considerable epidemic occurred in 1916 amongst Australian troops. Sir Philip Manson-Bahr, to whom I am very specially indebted for much help in the preparation of this paper, help from his book on "Tropical Diseases" and help given personally, was in Egypt at that time. He has told me about the incident, which he and N. H. Fairley investigated. The Light Horse had returned from Gallipoli in 1916 to the camp established for them at Tel-el-Kebir, a place which lies on the Eastern border of the Nile Delta and is about half-way between Cairo and the Suez Canal. Here they found a welcome chance of bathing in one of the main irrigation canals, and the troops who did so quickly began to suffer from skin irritation with an urticarial rash and an irregular temperature.

At that time very little was known about the transmission of the disease and still less about its treatment. For example, in Thompson-Walker's "Genito-Urinary Surgery" published in 1914 there is a good chapter on bilharziasis. To-day it seems strange that he pointed out that it was uncertain whether infection occurs through the stomach, the anus and urethra or through the skin. As to treatment it is frankly stated that "there is no known method of destroying the Schistosoma".

Information Service (health education institutes, public addresses, field health education, local and general health programmes).

This documentation is in my office at the Ministry of Health, and I shall be most happy to make the relevant sections available to any member interested in any particular problem or desirous of giving consideration to the possibility of applying it in his own work.

In conclusion I sincerely hope that as soon as ever circumstances permit it may be possible for many of my colleagues to go to the United States and avail themselves of the invariable kindness and generosity of the Americans in putting at our disposal full information regarding their technical progress and administrative experience.

FIG. 1.—Male and female *Schistosoma haematobium* Bilharz, 1852. M., male; F., female; E., egg; G.P., genital pore; I.B., intestinal branch; M.T., median trunk; O., ovary; O.D., oviduct; Oe., oesophagus; O.S., oral sucker; O., ootype; S.G., shell glands; U., uterus; V.G., yolk glands; V.S., ventral sucker. Insets, highly magnified parts of the skin of male.

FIG. 2.—Fuller developed cercaria of *Schistosoma haematobium*. A.C., alimentary canal; A.S., anterior sucker; B., bladder; C.D., cephalic gland ducts; C.G., cephalic glands; E.D., excretory duct; E.P., excretory pore; E.T., excretory tubule; F.C., flame cell; G.A., genital anlage; H.G., head gland; I.C., island of Cort; M.O., mouth opening; N.S., nervous system; V.S., ventral sucker.

blood cells. The male worm (fig. 1) is 1 to 1.5 cm. long, and about 1 mm. thick. He is provided with two suckers both of which are near the head end, and he uses these and the projections on the skin to provide himself with temporary attachments to the vessel wall and for movement. Throughout the greater part of its length the body of the male is split to form the gynæcophoric canal, and in this the female is embraced. The female is thinner than the male and about 0.5 cm. longer. She also has two suckers, one at the extreme head end, the anterior sucker, and another close to it known as the

During this war our troops have served in Egypt, East Africa, West Africa, and Rhodesia and the Union of South Africa, all countries in parts of which *Bilharzia hæmatobia* is indigenous. It is certain therefore that now, and perhaps still more frequently when the war is over, cases of this disease both in its acute condition and at other stages are to be expected in civil practice in this and other countries where usually it is never met with.

In this war I have served for two years in Egypt, and also for two years in East Africa where the disease is common in the native troops, and as a result I have acquired some knowledge of the manifestations of bilharziasis. This paper is, however, not written about my personal experience, and any value that it may possess is because it is a symposium of knowledge gathered from others who have had much longer experience, and whose names I shall mention. Officers in charge of medical and surgical divisions in East Africa and their officers, all working under the direction of Brigadier R. P. Cormack, D.M.S., E.A.C., and supervised by Brigadier E. R. Cullinan, the Consulting Physician there, and by myself whilst I was Consulting Surgeon in that Command, have recently made some notable contributions in the investigation of this disease, and also as to the immediate effects of treating large numbers of infected, though often uncomplaining, natives. The study of the results of ultimate cure will obviously take much longer to complete.

Discovery of the Parasite of Bilharzia.

Bilharz, a German who was Professor of Zoology in Cairo, discovered the parasite in 1851. Working on monkeys and later on man he demonstrated the worms in the portal veins of both. Another name which is widely used is *Schistosoma* (*Schistos* = divided, and *soma* = body), an allusion to the longitudinal split in the male which forms the gynæcophoric canal. There are three main species of Bilharzia: *B. hæmatobia*, the cause of the genito-urinary disease which we are now considering; *B. mansoni* the cause of one disease known as Egyptian splenomegaly, and also of another variety which is intestinal bilharziasis; *B. japonica* the cause of Eastern bilharziasis. This last variety, which affects chiefly the liver and spleen and is characterized by ascites, is confined to the territories which border the Western shores of the Pacific. The ova of the Eastern disease, *B. japonica*, are discharged in the fæces, as they are in the mansoni variety. *B. mansoni* has a somewhat similar distribution in Africa to hæmatobia, but unlike the other two forms it is also found in the north-eastern part of South America. After this war cases of all three varieties may appear in our clinics, and more than one may appear in the same patient. Therefore, when we are treating urinary bilharziasis we should cause examinations also to be made for *B. mansoni*, that is to say, we should send fæces for examination as well as the urine.

In this paper only *B. hæmatobia* is discussed.

In West Africa it occurs in the British territories of Sierra Leone, the Gold Coast and Nigeria. It is found all along the North Coast of Africa, also in Cyprus, and in a few places in Arabia including the Aden Hinterland and in Iraq. As for the remaining parts of Africa, the east and the south, it is often said that *B. hæmatobia* predominates in those territories whose waters drain into the Indian Ocean, the largest river being, of course, the Zambesi, whilst in the Congo basin the mansoni variety abounds. Though this statement is not completely accurate it has some clinical importance; anyone in Natal, Rhodesia or the Union will warn you of the prevalence of hæmatobia, and as soon as you cross the Congo-Nile divide into the Belgian Congo you will find that where people speak of "Bilharzia" they are referring to the commoner intestinal variety. In Uganda and Kenya *B. mansoni* is much the commoner disease, *B. hæmatobia* being chiefly, though by no means exclusively, found in the coastal area. Dr. Plum of the Colonial Medical Service found that about 50% of the population there had blood and eggs in their urines. Others have given higher figures, but it is difficult to decide the proportions of each disease for the rectal variety produces no dramatic symptoms such as hæmaturia, and probably 30% of the population of East Africa suffer from it, the majority quite uncomplainingly. In Egypt a large proportion of the population suffer from both diseases all their lives. *B. hæmatobia* has a wide distribution in the south-eastern parts of Africa. The region of the Cape is relatively free, yet L. B. Goldschmidt, the urologist practising in Capetown, tells me that of his European patients about one in fifty is admitted to a nursing home on account of this disease, or when under treatment there for some other condition is then found to be infected.

Life-history.

The life-history of the parasite of *B. hæmatobia* may be summarized as follows: The male and female worms having developed within the liver of man next migrate to the portal and mesenteric veins, particularly the inferior mesenteric. They live on the red

considered that it cannot live in the highlands, where the cold streams run down from the glaciers of Mt. Kenya. The snail host—*Planorbis*—of *B. mansoni* has, however, been found as high as 8,000 ft. in Kenya. Be that as it may, at any height above 6,000 ft. one does not hesitate to wade when fishing for trout. In Ceylon a snail of the *Bullinus* genus is said to exist, but *B. hæmatobia* does not occur. This seems curious, for long before the East African troops of this war trained in that island on their way to attack the Japanese in Burma, and in so doing may have shed miracidia into the streams, Arabian traders must have passed between Ceylon and Africa. There are species of *Physopsis* and *Bullinus* in many parts of the world, but most do not attract the miracidia. The ovum when washed out in the urine has to take a chance, but, if it is favoured by fortune, it does find and then attack the snail, boring its way through its antennæ and thus eventually obtains its objective, which is the liver or digestive gland of that mollusc.

Whilst resident in the snail's liver, sporocysts (fig. 8), which are transparent, tubelike bodies, are developed in large numbers from the miracidium. Within about fourteen days the next stage, the cercaria (fig. 9) (*κέρκος* = tail) is developed within the sporocyst. Eventually the snail dies of his disease, but before this occurs these cercariæ are discharged from it into the water. Under the stimulus of daylight they are puffed out in clouds from the snail's pulmonary cavity. This stage of the parasite, the cercaria, which is about twice the size of a bilharzial egg, swims by means of a bifid tail. The cercaria penetrates the human skin by means of a (lytic) destructive substance secreted by special penetration glands at its cephalic end, the part selected being usually that covering the legs of some man wading in the swamps, canals or rivers; or they may presumably get into a rat, mouse or monkey. Now they lose their tails and, travelling through the lymphatics and the blood-vessels, they reach the liver of the definitive host, and there develop into the male and female worms. This last phase, beginning from the time of entering the skin, takes about six weeks, and thus the astonishing life-cycle is completed.

Most of the research upon these parasites has been done in Egypt, an ideal land for their cycle. The disease can be proved to have existed there since the 20th Dynasty, that is 1250—1000 years B.C. Sir Marc Armand Ruffer, when he was working in Egypt on tropical diseases in 1910, examined six mummies of that dynasty. He soaked some of their organs and softened them in a solution containing glycerine. Then he cut microscopic sections and found terminal spined ova in the straight renal tubes of two mummies, this is particularly remarkable inasmuch as the kidneys are not so intensely invaded as the bladder. He did not examine the bladders because he judged them unsuitable for this method. Dr. J. G. Willmore of Queen Mary's Hospital, Roehampton was working with him at that time as a junior assistant, and tells me how he saw these preparations on many occasions.

In 1910 no one knew the life-cycle of the parasite, and even up to more recent dates it was believed that the disease entered the body through the urethra. The ancient Egyptians devised a cage to protect the penis. In the last war British troops in Egypt were advised to employ more modern methods. No doubt the Army Order containing the preventative instruction occasioned a good deal of ribald mirth, but this venerable Egyptian precaution has a sound basis, for Leiper remarks that in Egypt certain leeches sometimes enter the urethra and cause bleeding from it. No one seems to have attempted to protect the female sex at any time.

In recent years the disease assumed extremely serious proportions in Egypt, and it was estimated in 1939 by Scott, a Director in the Public Health Department of the Egyptian Government, as a result of 40,000 examinations, that half of the population resident in the lowest and widest part of the Delta of the Nile suffers from *B. hæmatobia*, and very large numbers are also infected with the mansoni variety. In that country the disease seems to have increased since more efficient methods, and in particular the building of the great Nile dams, have led to the irrigation of large tracts of the Delta throughout the year, instead of only during the periods of the Nile flood as in the years prior to 1820, and ultimately its ravages led to a serious shortage of labour. In 500 male autopsies Ferguson found that 8% died of bilharziasis. As a consequence of this a special activity was developed on the part of the Egyptian Medical Services in treating the disease amongst the fellahin, particularly in the children. *B. hæmatobia* has never been so great a menace to the native's health in any other country, and this is doubtless due to the peculiar methods of agriculture which prevail in Egypt. Nor in other lands does the disease commonly give rise to the advanced pathological conditions with which the surgeons of Egypt are so familiar. The cause of this difference is not clear, perhaps it is the constant and heavy reinfection of the fellahin which decides

ventral sucker, and immediately posterior to this is the genital opening from which the ova are discharged. Brigadier N. H. Fairley, now Consulting Physician to the Australian Forces, with Manson-Bahr during the epidemic amongst the Australians in 1916 worked out the manner in which the ova leave the female by making studies upon artificially-infected monkeys, the mesentery being exposed under anaesthesia. They observed the male embracing and fertilizing the female working his way by means of his suckers against the blood-stream of the portal vein, and thence along the mesenteric veins and its branches. He is impelled to undertake this arduous journey by an instinct derived during uncounted ages in order to ensure that his progeny may reach fresh water. Presently he enters a vessel near the bladder, but still at some distance from the mucosa, but one that is too small to admit of his further progress (fig. 2). Here his more slender mate slips from his embrace and continues to advance. The exact fate of the male is undetermined, and no one seems very interested in it. But sometimes the female rejoins him, and Christopherson and Fairley have recorded remarkable cases in which without reinfection the worms have existed in a patient for as long as thirty-seven years. The female now, by using her suckers, moves forward head first until she completely plugs and so tightly stretches a small venule that no blood can get past her. From her genital opening which is close to the ventral sucker she now deposits her eggs in a chain (fig. 3), retiring little by little in the process, and thus allowing the vein to collapse upon them. This collapse ensures that the ova, which have been laid so that their terminal spines are directed downstream, are given a tilt when the blood-stream is resumed and thus the spines become imbedded in the venule's walls. These eggs are minute—0.16 mm. by 0.06 mm.—that is to say about a third the size of a cheese-mite. Twenty or more ova may be deposited by one female on one occasion. In the course of the disease millions of eggs may be laid, and a heavily infected patient may discharge in the urine more than a thousand eggs a day. The egg-laying field of choice is the vesical submucous layer, few eggs are deposited in the muscular coats. Many eggs are also laid in the submucosa of the prostatic and penile urethra, as well as in other tissues of the genito-urinary tract. The spine being imbedded prevents the ova being washed away and some say that it is, by means of the spine that the vessel wall is perforated, others hold that the ovum escapes by the action of an enzyme which it secretes and which digests away a portion of the vessel wall (fig. 4). Clearly the ova at this stage have not yet reached the epithelial layer of the vesical mucosa. It is not known exactly how they do reach it but probably the muscular contractions of the bladder and the penetrating value of the spines bring it about that a large number of them eventually work their way to their appointed destination. Under experimental conditions in monkeys this may occur in a few hours. It is at this stage that the characteristic bilharzial tubercle (fig. 5), which is about the size of a pinhead, makes its appearance in the bladder mucosa, each tubercle consisting of a collection of perhaps twenty eggs.

At this stage each ovum contains the unhatched miracidium (fig. 6) which is the next unit in the parasite's life-history. There is some evidence, as pointed out by Ferguson when Professor of Pathology in Cairo, that the miracidium whilst it is still living within the ovum, produces some toxic substance which exudes and by causing destruction of the tissues in immediate contact enables the live ovum to escape into the urine. Soon after this liberation, if all has gone well, the ovum may find itself in suitable water, and the next venture begins. The difference in the osmotic pressure of the new environment causes the envelope of the ovum to rupture, and thereby the miracidium escapes. Nature has arranged that this does not occur in normal urine, but it should be noted that the hatching can be produced artificially by adding water to the urine. A. H. Harkness had a patient who achieved this for himself by drinking three pints of beer in quick succession, the urine which he then passed was so dilute that active miracidia were found to be disporting themselves in it in large numbers. Manson-Bahr has also seen this happen. This embryo—the miracidium—contains many germ cells, and it swims in the water by means of the cilia with which it is covered. Some primeval impulse attracts it to the intermediate host, a certain water snail, the *Bullinus contortus* (fig. 7) or to other varieties of that genus. This attraction appears to be chemiotactic and absolutely specific for a suitable type of snail. The miracidia is not attracted but actually repelled by other snails which do not offer a suitable nidus. This snail must be reached within thirty-six hours if the life-cycle is to continue, but it does not inhabit every stream in Africa. It abounds in the stagnant waters of the Delta clinging to aquatic plants, stones and posts. It cannot live in brackish water. It is rare in the Congo basin. It is particularly common in the shallow Great Lakes of Uganda, and others which drain into the headwaters of the Nile, though rare in Lake Victoria, a stretch of water so vast that perhaps the storms which sweep across it make its shores uncongenial to snails. In Kenya the snail is common near the coast but it is usually

INITIAL SYMPTOMS

When man is attacked by the cercaria he suffers immediately from a severe itching involving those parts which have been immersed. The irritation may be bad enough to cause him to leave the water. This is known as "Swimmer's Itch". A vesicular rash may appear, and following this the temperature becomes irregular, this may last five to six weeks and may resemble that of typhoid. After four to six weeks an urticarial rash occurs in patients in whom the infection has been very heavy and who are susceptible. It covers the whole body with areas of giant urticaria, and is generally considered to be a toxic manifestation. An eosinophilia appears with the urticarial rash rising to 10%, or even as high as 70%, varying not so much with the intensity of the infection as with the degree of the patient's response to it. It may be remarked that a leucocytosis of 50,000 to 60,000 also occurs. In a clear case now is a good moment to begin treatment with antimony, and without waiting for ova to be found in the urine. Pain in the liver is another symptom, due to its reaction to the invaders, a reaction by which many of them are destroyed. When the disease has invaded the bladder wall the patient presently suffers from hæmaturia. This may begin at any time from three months to two and a half years after infection. It is scanty and occurs at the end of micturition and is due to the rupture of small vessels brought about by bladder contractions. It is quite painless and in an uneducated patient attracts little attention. If the invasion of the bladder is rather more severe there may be slight frequency of micturition and a slight pricking sensation in the urethra.

Some lassitude and backache may occur as the disease of the bladder progresses, but it is usually only after a very long period that characteristic symptoms of cystitis develop. Anæmia is rarely obvious except in severe cases and when sepsis has become intense.

Examination of the urine.—The most general method of making a diagnosis of *B. hæmatobia* is to examine the last few drops of urine passed, or the centrifuged deposit of the urine of the patient, under a $2\frac{1}{3}$ inch or $1\frac{1}{6}$ inch objective. No staining is required. The ova with their terminal spines are easily recognized. They may be alive, dead, or sometimes calcified. Dr. Willmore considers that a specimen of urine is more likely to contain ova after exercise, and frequently gives the patient a spell upon the exercise bicycle before micturition. Until cystitis has occurred, and this is late in the disease, the urine except for the last few drops is clear to the naked eye unless blood be present. Until the disease is advanced abdominal and rectal examinations reveal no abnormalities. In the late stages the sclerosed bladder may be palpable in an emaciated patient, and *per rectum* extensive induration may be found to involve the prostate and vesicles, and all tissues at the bladder base and in the perineum. Cases in this country are, however, quite unlikely to show any such changes. The absence of such general signs adds to the importance of cystoscopy in diagnosis.

The importance of cystoscopy in diagnosis.—The finding of the ova in the urine of course proves the existence of the disease, but it must be realized that a failure to find them does not exclude it. The D.M.S. East African Command, Brigadier R. P. Cormack—as I have already mentioned—has formed a research committee to stimulate and control investigations in military hospitals. One object was to assess the value of cystoscopy as a means of diagnosis, and the officers under his command in medical and surgical divisions have by systematic investigation of large numbers of cases amongst African soldiers proved certain facts which may usefully be summarized here, for they are not generally known outside expert circles: (1) A solitary examination of the urine for ova is a quite unreliable test, for ova are not continually released from the lesions of the mucosa. (2) Five consecutive morning specimens, the last few drops of the urine being collected and centrifugalized, will in about 85% of cases show either ova, or red blood cells, the latter being strong evidence in the mass examination of natives that bilharzia is present. (3) Even in the absence of ova or red blood cells the continual presence of pus or of albumen in a native's urine means that a diagnosis of bilharzia is probable until it has been disproved. (4) Cystoscopy is the most accurate method of diagnosis in all active phases of bilharziasis. Moreover there are several characteristic vesical changes which persist when the active stages of the disease are past. It may be argued that cystoscopy does not reveal lesions of the kidneys and the urethral mucosa; that must be admitted, but it is probably very rarely that these tissues are affected without the bladder being also involved.

Cystoscopy is therefore a procedure which should never be omitted in a case which is suspected of *B. hæmatobia* but in which no ova have been found. I myself have cystoscoped many patients with active bilharzial cystitis both in Egypt and East Africa, whose urine examinations have been negative for ova. Nor should cystoscopy be

it. But we in this country must not assume that, because one of our people has acquired the disease elsewhere than in Egypt, it will, therefore, take a less serious form. An interesting point arises here—the children of Israel, when in Egypt, lived in the Land of Goshen (that is until Moses persuaded them to rebel in about 1300 B.C., possibly against Merneptah, son of Rameses II). This was the name given to an area in which Tel-el-Kebir to-day occupies roughly a central position. As has been mentioned the Australian troops contracted the disease in that very region in the last war, and it must always have abounded in these parasites, so that it seems certain that the Israelites cannot have escaped infection. It may seem strange, therefore, that amongst the various diseases, and the cleansings prescribed for them, particularly in the books of Exodus, Leviticus and Numbers, there is no mention of blood in the urine. Perhaps the explanation lies in the fact that the legal matter in these writings is much later than the narratives and is considered to have been chiefly composed and added at about 300 B.C. By this time, perhaps 1,600 years after the Exodus, the disease would obviously be rare amongst the Israelites, for the only part of Palestine in which it occurs is around Jaffa, and it would, therefore, not be considered worthy of mention by the priesthood. Another explanation is provided if we accept the opinion of certain Bible scholars who consider that the sojourn of Israel in Egypt is purely legendary.

Some knowledge as to the existence of bilharziasis in ancient Egypt may be gained from a study of certain papyri. I am greatly indebted for information on this subject to Professor Battiscombe Gunn, Professor of Egyptology in the University of Oxford. Six papyri dealing with medical matters are known to Egyptologists. The papyrus discovered by Professor Ebers in 1875 and known by his name is by far the most important of these. It is 20 metres long and 30 centimetres high. It is possible to fix with considerable accuracy the date of its compilation as approximately 1550 B.C. The contents have almost certainly been written by a professional scribe; they were already of considerable antiquity when he did this, and it may well have been a unique assemblage of material made for the use of a practitioner of those days. The original authors of the various portions of the papyrus were no doubt themselves physicians, for these formed a quite definite professional class in ancient Egyptian society, though they had to be magicians as well as medical men, since a large part of the treatment of diseases consisted in a recitation of spells and of magical rites. Much of the papyrus is devoted to lists of prescriptions consisting of various plants, parts of animals, minerals, liquids, and other components, but it is by no means all of this character; for example, it contains a lengthy dissertation upon the heart and the blood-vessels, in which occurs the statement that "when any physician, any surgeon palpates the head, hands, abdomen, feet, &c., he examines them because of the heart, for all the limbs possess its vessels, the heart speaks out of the vessels of every limb." This seems to suggest some considerable understanding of the vascular system.

The detailed translation of a document is obviously a matter for an Egyptologist with medical knowledge, and this was done from a hieroglyphic transcript of the original hieratic writing by Dr. B. Ebbell of Norway in 1936. The meaning of certain words in the language of ancient Egypt is still unknown. There is one word which concerns us particularly. It can best be rendered into English letters as 'a'a. Because of the way in which it is written and the contexts in which it occurs Ebbell and other experts agree that it signifies hæmaturia, indeed no other interpretation is possible, though I personally would suggest that it includes also hæmopermia. The Ebers Papyrus contains twenty prescriptions for the treatment of the malady. Another papyrus, the Berlin Medical Papyrus, contains eleven such prescriptions, and the Hearst Papyrus contains eight. This seems clear evidence that bilharziasis was an important disease in the days of those ancient dynasties. One prescription runs as follows: To expel hæmaturia caused by a god or a dead man in the belly of a man, juice of acacia, juice of pistacia, salt, grapes, honey (and some other items not identifiable) are mixed together and eaten before going to bed.

Ebbell believes that the ancient Egyptians knew that worms caused this disease; he points out that they had opportunities for discovering them during the process of embalming. Among the recipes prescribed for intestinal worms is one which says: "To be eaten by a man in whose belly there are *hereret* worms; it is hæmaturia that creates them; they do not die as the result of any remedy." The worm called *hereret* has not been identified with certainty, yet although cause and effect are transposed, this statement suggests that already in antiquity the Egyptians had observed the schistosomes. Although antimony is alluded to in a composition for dressing for the hair and was also much used for painting the eyes, there is no mention of it as a drug in the treatment of hæmaturia. This is not surprising, as it is of course only effective against bilharziasis when used parenterally.

CLINICAL ASPECTS OF BILHARZIASIS

Post-mortem Examination and Diagnosis.

Dr. Willmore tells me that the easiest way to find the parasite at a post-mortem examination is to incise the portal vein, and to let the blood flow into a flat glass dish, whilst the liver is squeezed. Then dilute the blood with water, rocking it and holding it over a dark surface; in this manner the worms can be seen, resembling minute white threads, usually being curled upon themselves, and, as has been mentioned, they are about the size of the smallest pin. F. M. Sandwith, consulting physician to the Kasr-el-Aini Hospital, Cairo, writing in 1901 reported finding 436 worms in the blood from one liver.

FIG. 2.—Section of male and female worms in copula in the vessels of a retrovesical lymphatic gland. The female on the left side is cut twice and the male appears as if embracing two females. The veins remain open as if arteries. Notice deposition of pigment in all vessels to the point of occlusion.

FIG. 3.—Deposition of eggs by *B. haematobium* in blood-vessels and their passage to exterior. 1, Anterior sucker; 2, posterior sucker; 3, vaginal orifice; 4, uterus with contained eggs.

FIG. 4.—Venule of submucosa of bladder, showing an ovum just attached to endothelium by fibrin O, and another midway in endothelium (E). A third one (X) is on the point of leaving the endothelium. L, lumen of vessel. Note that the ova are escaping sideways, the spine playing no part in the process.

omitted when the existence of the disease has been established by the finding of ova in the urine, for it gives a measure of the intensity of the infection, it may reveal important complications and it is a check on the efficacy of treatment. Of course when whole populations of adults and children are affected cystoscopy is not practicable, but during this war it has been used to an extent never hitherto attempted, and with proved value in the treatment of native troops of East Africa. Certainly any urologist practising in this country should make use of it.

Cystoscopic appearances in vesical bilharziasis.—The earliest abnormality seen in the bladder mucosa is the appearance of patches of congestion which occur most commonly in the trigonal region, these, however, have no characteristics which enable certain diagnosis to be made. Subsequent stages are specific and are particularly well illustrated in a paper, "Cystoscopic Appearances of Bilharziasis of the Bladder", by Naguib Makar, F.R.C.S.Eng., Professor of Urology, Faculty of Medicine, Kasr-el-Aini Hospital, Cairo. A selection of these are here reproduced with his kind permission (*see* colour plates).

The first of these stages is very typical. Bilharzial tubercles make their appearance. Each of these is about as large as is the tubercle due to Koch's bacillus, to which it bears some resemblance, that is to say about the size of a pin's head. It is raised above the level of the mucosa and is surrounded by a narrow ring of congested vessels. It has a shining surface and a faintly yellow colour. As it grows and dies the shine diminishes, the yellow colour remains and is sometimes intensified, whilst the surrounding hyperemia becomes less or may disappear entirely. The bladder mucosa which lies around a collection of these tubercles is sometimes congested but maybe very little different from the normal. When an intense invasion by ova is in progress very marked bullous oedema (fig. 22) is often produced. It is difficult to say how much this is a mere reaction to the ova and their toxins, and how much it is due to venous blockage by the worms, but probably the former is the more important cause.

Bilharzial nodules (fig. 11) are larger than tubercles, they are more prominent and greyer in colour, and are more commonly met with in chronically infected bladders. The tubercles may also fuse and give rise to a membrane (fig. 12) which at first has an orange colour, but later becomes grey. The membrane is composed of blood, mucus, epithelial debris and ova. It is very adherent; if detached an erosion is exposed. An area so infected is surrounded by congestion.

These cystoscopic appearances are very characteristic of the disease, and are unlikely to be missed by any experienced urologist, even if he has never before met with a case of vesical bilharziasis.

Some of the later changes are much more difficult to interpret. The examination of a patient with active and advanced lesions is also less easy and it is usually necessary that an anæsthetic be given and a flushing cystoscope employed. In mild and in chronic cases there is, however, one special detail well worthy of the urologist's attention. Sometimes all the fields inspected when looking through the cystoscope in a downward, or in either lateral position, and the region of the bubble are found to be normal. If, however, by a very full depression of the eyepiece the anterior aspect of the bladder be examined, and particularly that part of it which is about half-way between the bubble and the internal meatus, a solitary patch of mucosa affected with bilharziasis may be discovered. Sometimes tubercles are seen here, sometimes only congestion or sandy patches or granulations. This we learnt for ourselves in Egypt where all our cases were Europeans, most of them having been infected in South Africa or Rhodesia, patients who of course reported for examination with symptoms of mild degree. In East Africa also when cystoscopy otherwise healthy native troops who were suspected to have the disease we never omitted to examine this area in detail, that is to say the region of the bubble and the parts anterior to it.

Bilharziasis of the bladder may develop in various ways from these earliest states. The live ova from a tubercle or other infected area of the bladder work their way through the ultimate mucosal covering and are thus shed into the urine, the tubercle then dies a natural death and the healed area leaves no permanent scar. Alternatively dead ova which have not been discharged may remain as tubercles for a long time, but for just how long I do not know (fig. 23).

Calcification of the bladder tissues around the ova is a prominent feature in all severely infected long-standing and untreated cases. In Kasr-el-Aini Hospital, Cairo, X-rays demonstrate calcification in 60% of bladders affected with bilharziasis. It has already been mentioned that the ova when alive are believed to secrete a toxic substance, the function of this being to cause dissolution of the surrounding tissues and thus the release of the ovum into the urine, and it seems very probable that it is this "toxin" which by prolonged action produces the intense sclerosis of the bladder wall, which ultimately goes on to calcification, for it seems unlikely that the ova acting merely as foreign bodies could produce this result.

FIG. 5.—Bilharzial tubercle of the bladder wall with ova, some calcified, in the tissues.
(After Ferguson.)

FIG. 21.—Calcification in submucous layer of bladder wall.

One local result of calcification is what is called sandy patches (fig. 13) in the mucosa. Nowadays this term is used to describe characteristic cystoscopic appearances, areas looking like sand under water, produced, as pointed out by F. C. Madden, by aggregations of calcified old tubercles, the epithelium having degenerated. But the name "sandy patch" is much older than the cystoscope, for Dr. Willmore tells me that it was employed to describe the grating felt when cutting through such areas with a knife, or the grittiness elicited with an urethral sound when moved against the trigone and the bladder base. In those early days, though not now, this was a justifiable method of diagnosis, particularly when following such instrumentation it was found that the ova could often be detected in the urine.

The process of calcification affects chiefly the submucous layer of the bladder wall (fig. 21). It is by no means necessarily accompanied by secondary infection, and on cystoscopy in such cases I have often seen the bladder to be clean. If so it is usually very pale owing to sclerosis and diminution of the vessels. This calcification forms a barrier in which many ova perish, and through which others cannot work their way. But though it may break the life-cycle of the parasite, and though it may shield the patient from the pangs of bladder disease, it does not mean that he is cured of his bilharziasis. For if the worms do not die their ova will still continue to attempt to reach the urinary channels, and so do still more damage to the deeper layers of the bladder and to neighbouring tissues. In such cases either cystoscopy or X-ray should make a diagnosis certain, but urine examination will usually fail, for even if the disease is still active and ova are present they cannot necessarily force this barrier. Patients afflicted with the disease in this form often have only symptoms of limited vesical capacity. L. B. Goldschmidt says that such bladders, even when some evidence of calcification is found on X-ray, can often be successfully dilated under spinal anaesthesia. Such treatment would not, of course, be undertaken until antimony had completed its curative effects.

Another stage is the development of a bilharzial ulcer (fig. 14). This may be clean and without sloughs. It is usually single, and Makar says that he has never seen this type of ulcer become malignant. More often secondary infection is co-existent, and in such cases an ulcer, also usually a solitary one, has a sloughing base and marked cystitis is present.

Secondary infection is very common in Egypt, but is much less often met with in East Africa. In its worst form it leads to a degree of cystitis more severe than in any other disease. The bladder becomes intensely contracted and filled with blood-stained, sloughing, oedematous and shaggy masses of mucosa which resemble a secondarily infected carcinoma, from which it may be very difficult to distinguish.

When large numbers of the ova collect in the submucous layer they may cause tumour-like bilharzial masses (figs. 15 and 16) to project into the bladder. These are composed of fibrous granulation tissue packed with eggs. Tubercles are often seen on the surface of these masses, from which ova are commonly shed in plenty. Such masses are not neoplasms and must be distinguished from them. This condition can be cured by anti-bilharzial treatment. That the distinction is not always easy may be illustrated by a story of a urologist of this country who was about to perform partial cystectomy for carcinoma upon an Egyptian when a cable from relations in the patient's home town requested examination of the urine for bilharzia. This A. H. Harkness was asked to undertake, he did so, found the ova, and later dispersed the tumour with antimony.

Vesical papillomata (fig. 17) due to bilharzia are common in Egypt. This is a true neoplastic condition and frequently malignant. In that country cancer of other organs is uncommon, and these growths are considered to be the result of the "toxins" of the ova. In two years at the Kasr-el-Aini Hospital out of 130 cases of carcinoma of the bladder 114 were of the papilliferous type, and the great majority of these were judged to be the result of bilharzial disease. Twenty-two occurred in patients under 30 years, fifty-seven in patients between 30 and 40 years. One hundred and seventeen were males, thirteen were females. One hundred and ten occurred in field labourers. Makar says, however, that bilharzial cancer is also not rare in the upper classes of Egypt. A bilharzial papilloma, unlike a granulomatous mass with which it sometimes may be confused, is of course not to be cured by medical treatment. These growths do not have long fronds but are of firm consistency (fig. 18). Usually there are only two or three of them. The commonest variety of bilharzial papilloma met with in Egypt is of bulbar form and dark red colour though in parts it has a greyish-white appearance due to septic necrosis and to phosphatic deposit in the growth. These growths may spread and in rare cases involve the greater part of the bladder. Nodular infiltrating carcinomata (fig. 19) are less common. In the series of one hundred and thirty cases and follows the course common to all bladder carcinoma of this type.

PLATE VI
(for acknowledgments see text)

FIG. 5.—Bilharzial tubercle of the bladder wall with ova, some calcified, in the tissues.
(After Ferguson.)

FIG. 21.—Calcification in submucous layer of bladder wall.

Radiography is a useful aid to diagnosis in this condition. X-rays of the pelvis may show, as has been said, calcification throughout the wall of the bladder, often only as a fine line of opacity (fig. 21), but this is not necessarily present. Calcification may also be seen in the lower ureters. Excretion X-ray urography, however, shows the lower parts of the ureters to be dilated and the strictures to be either at the entrance to the bladder, or one or two inches above that part. In later stages the ureters may be dilated throughout their lengths and hydronephrosis may be present, these are sometimes of severe degree. The best method of diagnosis when a stricture is suspected is the passage of a bulb-ended ureteric bougie, for this will prove conclusively its presence or its absence.

TREATMENT OF STRICTURES OF THE URETER

Dilatation of an established stricture of the ureter is best effected through an instrument of the McCarthy panendoscope type, using some form of stiff ureteric dilator. Such methods when possible are very effective, more so it seems to me than in any other types of ureteric strictures, and though the case requires further supervision the cure is often complete. L. B. Goldschmidt confirms this opinion and says that he has only thrice found it necessary to open the bladder in order to treat resistant strictures. But such conditions do exist and will obviously occur most frequently in territories in which the disease is specially prevalent, and when no bougie can be passed treatment is, of course, more difficult. I am indebted to Mr. H. Currie Brayshaw of Johannesburg for an account of the operative technique to be employed in certain selected cases:

"In bad strictures one can occasionally do a meatotomy using a Collin's electrode, but often the strictures are higher up and one has to rely on dilatation. In these cases where even the finest filiform bougie cannot be passed, or where the ureteric orifice cannot be found despite indigo carmine, then open operation is resorted to. The ureters are exposed extraperitoneally through a mid-line incision, and the bladder is also opened. The dilated ureter is incised above the stricture and attempts are made to pass a filiform guide, and if successful a gum-elastic bougie is next passed. Then from the intravesical aspect an incision is made through the mucosa of the ureteric orifice on to the bougie, thus splitting the ureteric opening wide open. Larger bougies are then passed. A stitch is now put on either side through the cut made in the ureteric orifice. A small rubber tube (14 French catheter gauge) with numerous side holes is then passed up the ureter to the renal pelvis and a retaining stitch of catgut is inserted through the mucosa at the ureteric orifice, which also picks up the rubber tube. The extraperitoneal incision in the upper part of the ureter is stitched with continuous catgut, a de Pezzer tube inserted into the bladder, and this with the lower portions of the two ureteric tubes is brought out through the abdominal wall. Drains of soft rubber are placed down to each ureter where they were incised and into the cave of Retzius. In cases where the filiform bougie cannot be passed through the stricture into the bladder, a 3/5 English metal bougie is passed down to the stricture, and where this is caused to project under the mucosa of the bladder an incision is made on to it and the bougie is then forced into the bladder. The remainder of the operation then follows the course already described. If the strictures are several centimetres above the bladder, the ureter may have to be divided and transplanted into the bladder (using the cuff technique of Van der Veen)."

TREATMENT

I do not propose to discuss the general treatment of urinary bilharziasis, or of the later complications of the disease. Until treatment with antimony sodium tartrate was introduced by McDonagh (1912) and Christopherson in 1917 there was no known cure for the disease, and therefore no hope for the 90% of the fellahin who were infected. Filix mas was employed without effect except sometimes to cause blindness, for it often was used in conjunction with castor oil in which it is very soluble, and thus it produced a degeneration of the retinal vessels. Thymol was also tried but without availing anything. Bladder washes with solutions of quassia occasionally liberated worms, and sometimes appeared to relieve symptoms. Surgical relief of urethral obstruction was often required, also operations for calculus, clot retention and severe degrees of contracted bladder. Frequently this was all that could be done for the patient. Dr. Willmore tells me that he has performed Cock's perineal puncture in hundreds of cases, the bladder being too contracted to admit of suprapubic approach. Since those days much has been done in Egypt to cure the disease, particularly by treating the school children, and many attempts have been made to eliminate it. Of the latter the most important is the periodic closing of the irrigation canals, the mud is then dug out and allowed to dry on the banks under the sun, a process which kills the snails.

Tartar emetic remains the best drug, despite some unpleasant effects experienced by the patient during the period of administration. The course should amount to a total of 30 grains, and it must be intensive lest the parasites acquire a resistance to antimony. There are also some more recent preparations such as stibophenum, anthiontaline and fowadin. These are administered intramuscularly, and this is of great value in the

Amongst the primitive population of the Nile Delta these malignant growths often produce great extensions and also widespread metastases before the patient reaches the hospital, and in such cases the symptoms of pain, strangury, frequency and bleeding attain most severe degrees. Sarcoma is rare, but Ferguson found six instances amongst two hundred and forty post-mortem cases of vesical bilharziasis.

URINARY OBSTRUCTION AND FISTULÆ

In untreated cases the musculature of the bladder which is the seat of this disease tends to be thickened, partly owing to hypertrophy and partly because of fibrosis by the additional development of prostatic and urethral obstruction, resulting from bilharzial changes in those tissues. Despite such obstruction the bladder in these cases often remains contracted, and if so this renders suprapubic cystotomy very difficult or impossible to perform. To-day the most advanced degrees of obstruction are probably less common in Egypt than they were in the days before antimony was used as a cure. So also are urinary fistulæ which are a direct result of the disease. These affect all parts, but particularly the floor of the urethral bulb, and are often so numerous and extensive that when the male patient squats to micturate the perineal effect resembles the spraying from the rose of a watering-can. These fistulæ sometimes track widely. Willmore once saw one patient who could micturate only through an opening at antero-internal aspect of the knee. In 1901 Sandwith found that 14% of the bilharzia cases in the Cairo hospital suffered from fistulæ of the bladder or urethra. Ova are often found in the fistulous tracks.

Vesical calculi are met with in bilharziasis and the ova have been in rare cases found within the stones, for example Goebel found certain ova in 8 out of 68 calculi. In 1901 Sandwith reported 14% of bilharzial cases at the Kasr-el-Aini had calculi, more recent reports give a lower percentage. These calculi appear to be composed of uric acid and oxalates, and are formed upon debris. Phosphatic calculi are very common when sepsis has become severe. Renal calculi are also met with, though they are very much less frequent. It is of interest that Elliot Smith, who with Wood-Jones examined, or studied records of about 30,000 mummies, found only two examples of vesical calculus and three of renal calculi. This may be interpreted to mean that modern methods of irrigation in the Nile Delta have greatly increased the incidence of the disease; I think a more probable though partial explanation is that only the bodies of the upper classes were embalmed, and these personages ran much less risk of infection than the labourers in the fields. Nevertheless the discrepancy is very remarkable. Shattock failed to find ova in two of these calculi despite laborious research.

Death amongst the fellahin affected with this disease who have not been effectively treated is due to extreme suffering resulting from bladders secondarily infected, to uræmic sepsis, or to malignant disease. In East Africa such conditions are rarely met with, probably because the infection is much less severe.

OBSTRUCTION OF THE URETERS

Ureteric obstruction of moderate degree is often met with during the active stage of the disease. In such cases it will disappear when a course of treatment with antimony has had time to kill the worms and thus cause the acute reactive processes to resolve. As a result of this the usual symptoms of aching pain in the loin or colics are relieved.

Chronic ureteric stricture is a very important and frequently insidious result of bilharziasis and one which we must be prepared to diagnose and to treat. It affects the lower parts of the duct, for the upper portions lie in an area which is but rarely invaded by the worms. Most of the various pathological conditions which arise in the vesical mucosa may also be met with in the ureters (fig. 20), but stenosis is the common complication and though it may sink into relative insignificance in the clinical picture of a native affected by advanced urinary bilharziasis, yet in such patients death from infected bilateral hydronephrosis is common. These strictures, however, are met with in patients who appear at first sight to have recovered completely from the disease. I have had experience of a good many of such cases. The patient may have no bladder symptoms, he may or may not have suffered from renal colic, ova may not be found in the urine, and on cystoscopy there may be no active bilharzial lesions. Typically in such cases the vesical mucosa is unduly pale and very few vessels, sometimes none, are to be seen; the surface may be smooth or it may be slightly roughened, fasciculations and sandy patches may be present, but often there are none. The ureteric orifices at this stage are often not inflamed but they are rigid and they look lifeless, they are not retracted and do not resemble the dark golf-hole ureter of renal tuberculosis.

Section of the History of Medicine

President—Sir ARTHUR MACNALT, K.C.B., M.D.

[November 1, 1944]

The Medical Career of Jean-Paul Marat.

By H. P. BAYON, M.D.

THE "Friend of the People" has been considered an eminent physician or a low-down quack, according to whether the writer admires or condemns Marat's political activities from 1790 to 1793; for it was only then that he became known as the "tiger that would have drunk the blood of his mother from the skull of his father". Previous to these revolutionary years, Jean-Paul was a whole-hearted admirer of Jean Jacques Rousseau (1715-78) that is, a mild humanitarian—in theory. To obtain a complete picture, reference must be made to Marat's works on heat, light and electricity, since he was a keen scientific experimenter during most of his life.

Existing documentation provides a clear impression of "Dr. Marat's" qualifications and practice, so that his significance in relation to medical and scientific progress can be ascertained.

BIOGRAPHICAL NOTES

His father, Giovanni Mara of Cagliari, Sardinia, was an artist or designer and teacher of languages; he married Louise Cabrol of Geneva, the daughter of a wig-maker; these occupations explain some obscure periods in Marat's life, for it has been suggested that at one time he taught "tambouring", i.e. designs for embroidery, and that he had been a hairdresser.

Jean-Paul Marat was born at Boudry, Neuchâtel, May 24, 1743, and at the age of 16 left home to become tutor to a family in Bordeaux; it was probably then that he added a "t" to his name, so as to Frenchify it. He left two years afterwards and it is uncertain what he did or how he lived till he came to London some time in 1766-67; for this we have evidence from Farington's Diary—December 6, 1793—where it is recorded that Marat lodged in St. Martin's Lane and said that he was in England to complete his studies; that he was friendly with Antonio Pietro Zucchi (1726-95)—who later married Angelica Kauffmann—and borrowed £500 from him; medically cured and treated Joseph Bonomi (1759-1808). Where Marat obtained his medical knowledge is unknown; it can be assumed that he was an autodidact by books. Farington mentioned that an apothecary told him that Marat did not conform to common usage in his prescriptions.

After five years residence in Great Britain his first work was published anonymously: *An Essay on the Human Soul* (1772), in this he quoted Albrecht von Haller (1708-77), whom he may have met and several other authorities that were dead—like Boerhaave (1668-1738), Théophile Bonet (1620-80). In this essay, Marat suggested that there were seven senses; to the usual five he added hunger and thirst; he said that nerves carried two fluids, one sensory and the other motor; his evidence was that when a nerve was tied, sensation and motility ceased; he placed the soul in the meningeal membranes. Modern concepts of the soul differ from those of his time, but it is known that by peeling off the *pia mater* the higher faculties of the brain may be impaired; this is, however, due to the resulting lesions to the small blood-vessels and the concurrent circulatory disturbances.

It was in 1811 that Sir Charles Bell (1774-1842) separated the functions of the roots of the spinal nerves and even then, clearly visualizing the function of the anterior roots alone. He completed his discoveries later, recording them in his book on the nervous system in 1830; but meanwhile, in 1822, Francis Magendie (1785-1855) had published experimental proof of the separate different functions of the nerves.

treatment of the school children of the Delta. They obviously have advantages when large numbers of troops have to be treated but they are not considered to be so certainly curative as is antimony sodium tartrate. Antimony first sterilizes the generative apparatus of the female worms and ultimately destroys them. It is not known just how certain is the effect upon those ova which have been deposited before treatment was begun.

My only case of bilharziasis in pre-war years was a young man, aged 20, who was infected after spending just over one year in a place about 70 miles distant from Salisbury, the capital of Southern Rhodesia. This is a country where bilharzia is well known yet his fever, hæmaturia with the passage of clots of blood, and once an unexplained attack of retention of urine for thirty-six hours, had remained undiagnosed. He came to see me when he returned to England. I sent his urine to Dr. Cuthbert Dukes, and he found the ova. When I cystoscoped him the appearances were typical (figs. 22 and 23). He was treated by Dr. J. B. Christopherson who cured him with tartar emetic.

It will be agreed that we must keep our eyes open for occasional cases of this disease. Not only have officers and men of all three Services served in countries where this disease is endemic, but there also are to be remembered the children of those of our people who at all times follow their occupations in these territories. It is not only the unalluring channels of the Sweet Water Canal which harbour the disease.

A doctor friend of mine, who was brought up in Pietermaritzburg, Natal, tells me that he was educated there in a school of 600 boys, they all bathed in the neighbouring river, and 70% of them had terminal hæmaturia. He himself suffered from this all the time he was a medical student and during the last war, with occasional attacks of renal colic, which were followed by the passage of a clot or a small oxalate stone. He was one of the first cases to be cured by Christopherson with antimony.

Egypt, the territories of the Union of South Africa, and East Africa are all places where the British race makes its home, and in all the disease may be acquired though the Highlands of Kenya are relatively immune. Therefore a history of service in any of these places may be important when bladder disease is being investigated. Urologists must, therefore, know how to diagnose the early stages of bilharziasis, whilst its later manifestations will remain chiefly a matter of general interest. Failure to demonstrate the ova in the urine, particularly in a solitary specimen, does not exclude the disease. Cystoscopy takes a high place in diagnosis in every stage of the disease, and is of great importance in the control of treatment. The insidious danger of ureteric obstruction occurring when all signs of active parasitic infection have faded from the scene must not be forgotten. Moreover we must be aware of the fact that the worms, when their normal vein paths are obstructed, may find their way to the seminal vesicles causing hæmospermia, also to the prostate (Goldschmidt has found ova in tissues removed by prostatic resection), vas, epididymis, testis and tunica vaginalis, and produce sclerosing or infiltrative changes in these organs. Finally we must not forget that a patient who has become infected with *B. hæmatobia* may well have become invaded by *B. mansoni* at the same time.

ACKNOWLEDGMENTS

Special thanks are due to Dr. Naguib Makar, F.R.C.S. Eng., Professor of Urology of the Faculty of Medicine, Cairo, for the loan of the paintings for figs. 10 to 17 which illustrated his paper on bilharziasis of the bladder in the *Journal of the Egyptian Medical Association*, 1932, and for figs. 18 and 19 which appeared in "A Preliminary Note on Bilharzial Cancer of the Bladder", published by the Ministry of Public Health, Egypt, 1938. Figs. 5 and 21 also appeared in this publication.

Figs. 1, 2, 4, 6 and 8 are reproduced from "Schistosomiasis", by Rameses Girges, by kind permission of the publishers, Messrs. John Bale Medical Publications Limited. Figs. 3 and 7 are from "Manson's Tropical Diseases" by courtesy of Sir Philip Manson-Bahr and Messrs. Cassell & Co., who have also kindly lent the colour blocks for figs. 22 and 23.

and seemingly obtained considerable improvement. In the third patient Marat mentioned "a scorbutic habit" which was cured by "anti-scorbutic Remedies" such as water-cresses, bitter plants, &c. In both tracts there is no lasting contribution to the pathology or therapy of the diseases treated; it is quite believable that by persistent care and attention, Marat did obtain a definite measure of success in these cases. What is most remarkable is that no one would recognize in the obsequious, candid style of these communications, the hand of the bloodthirsty Deputy of *La Montagne* in the Convention of Paris.

Phipson in 1924 ascertained that Marat was not a householder in Church Street, Soho; the prefaces of the two tracts having been dated from there is no evidence whatever that Marat carried on a flourishing medical practice from that address, nor are the dates any proof that Marat was there at the time.

It was at this time that a remarkable incident occurred in Marat's life, no less than a theft from the Ashmolean Museum, Oxford, and his conviction to the hulks at Woolwich. All this has been denied by the majority of his biographers, but the clear evidence available will be quoted elsewhere in the near future.

What is relevant to Marat's medical career is that in May 1777 he was in Paris and called to treat the Marquise de Laubespine, who was suffering from phthisis, as a physician *lately* arrived from England.

A few words may be said about Mme de Laubespine, whose case is described by Cabanès, "*Marat Inconnu*" Paris, in Chapter VIII entitled: *Marat et les femmes*; but here we prefer to examine her case as one of pulmonary tuberculosis. That she really suffered from the disease can be accepted; five years before she had developed a dry cough, shortly after a confinement; this may well have been the flaring-up of a cryptic infection following pregnancy—a not uncommon occurrence. Notwithstanding treatment, the disease progressed, the patient lost weight, expectoration became purulent. When Marat undertook treatment, he prescribed an emulsion of almonds with salts of nitre, to which he added a secret remedy, which subsequent analysis showed to be an artificial mineral water, similar to that of Harrogate. Then followed laxatives in the shape of "*Sels de policreste*"; further, quinine extracts and Peru balsam, together with fifty drops of ambergris in a cup of cow's milk every morning. Marat does not appear to have performed percussion or auscultation, though Leopold Auenbrugger's (1722-1809) book *Inventum novum* had appeared in 1761 and had been translated into French by Rosière de la Chassagne in 1770. This useful diagnostic method had to be revived in 1808 by Jean-Nicholas Corvisart (1755-1821).

In any case in June and July of 1777 the Marquise was considered to be cured; four years afterwards she was still alive, but her subsequent life-history is unknown; her sudden improvement may well have been due to one of those remissions with temporary relief that occur in tuberculosis of the lungs. Whatever the explanation may have been, Marat's success was skilfully advertised in the *Gazette de Santé* in an article by the Abbé Fillassier [? Jacques Joseph Fillassier (1745-99) author and great admirer of Rousseau]. Unfavourable critics also wrote to the *Gazette* and the Marquis de Laubespine replied, defending Marat, who also took part in the debate in December 1777.

It was Mme de Laubespine who recommended Marat to the Comte d'Artois, who then appointed Jean-Paul Marat, "a Doctor of medicine of several faculties in England" as *Médecin du Corps des Gardes* with a brevet dated June 24, 1777—which Cabanès reproduced in facsimile—pp. 104-5.

In consequence of all this, Marat was approached by several patients and entered into correspondence with others outside Paris: soon after Marat was living in an elegant apartment in the Faubourg St. Germain; his practice may well have been extensive and lucrative. How long this prosperity lasted can be approximately ascertained, because by 1783 he was trying very hard to obtain the position as head of a newly formed academy in Madrid and showed a great interest in all things Spanish. He said that his practice had suffered as the result of professional jealousy and slanders—that medicine gave him no satisfaction, when compared with the pursuit of scientific aims. He was not accepted for this post, because some French Académicians spoke and wrote against him; this is quite believable.

Next year Marat's last medical writing was published: *Mémoire sur l'électricité médicale. Couronné le 6. Août 1783, par l'Académie Royale des Sciences, Belles Lettres & Arts de Rouen* (Paris, 1784), Jorry. This is probably the best piece of work Marat did; it is mainly concerned with contesting the effects of electricity on various diseases; on p. 2 he mentioned: "... des prétendus miracles opérés par les mains des Pivati, des Verrati, des Brigoti, des Bianchi, &c." Much is also said about Abbé Bertholon, who had stated that fever was due to an excess of electricity in the blood. This was Pierre Bertholon (1742-1800) author of: *De l'électricité du corps humain dans l'état de santé et de maladie. Ouvrage couronné par l'Académie de Lyon*. Two vols. (Paris,

Most biographies of Marat—and there are many—mention that he sent one of his works to Professor Collignon of Cambridge, who wrote praising the book. I have traced Charles Collignon (1725-85), M.D., F.R.S., professor of anatomy, author of: *An Enquiry into the Structure of the Human Body Relative to its Supposed Influence on the Morals of Mankind* (Cambridge, Second Edition, 1764-65), Bentham. *Medicina Politica or Reflections on the Art of Physic as Inseparably Connected with the Prosperity of a State* (Cambridge, 1765), Bentham.

Collignon wrote to Marat on May 1, 1773, a somewhat thin-lipped acknowledgment of the *Essay on the Human Soul* which Marat translated and added to his letter to Philippe-Rose Roume de St. Laurent in 1783. It should be noted that Vellay (1908), p. 49, gives the reference of Collignon to a "somewhat lively description" as occurring on page 857—it obviously should be page 257, Vol. I of the *Essay*.

In Vellay (1908), p. 12, there is the translation of a letter of Marat to a Mr. William Daly, dated from Paris, "December" no year. From the fact that Marat begged to be excused for his faulty English it can be surmised that it was written in the first years of his residence in Great Britain. In it, Marat said that his heart was "as tender as yours"; then explained why he anatomized animals for medical and surgical purposes; that he foresaw the time when experiments on animals would be as universally adopted in France as in England; that he could obtain many cadavers and announced the early appearance next year of his work. He invited Mr. Daly to come and study with him in Paris. At this time (? 1770) it is more than probable that he tried to obtain the acquaintance of John (1728-93) or William Hunter (1718-83) who in 1768 had built the Museum in Great Windmill Street.

So far there is no evidence that Marat was established as a regular medical practitioner in London, but it can be accepted that he practised human and veterinary medicine in Newcastle some time between 1772 and 1774.

The same year Marat went to Holland and, on his way back, stayed in Edinburgh during June and August 1775; it was then that he obtained the degree of M.D. from the University of St. Andrews on the strength of being an *Artium magister*—which seems to have been a bit of wishful thinking; it was of this University that Dr. Samuel Johnson remarked that it had become wealthy by degrees.

Then Marat's first medical tract made its appearance: *An Essay on Gleets. The Defects of the Actual Method of Treating Those Complaints of the Urethra are Pointed Out, and an Effectual Way of Curing Them Indicated* (London; printed for W. Nicoll—no date). This was dedicated from Church Street, Soho, November 21, 1775, to the Worshipful Company of Surgeons in London. The two known copies are in the Library of the Wellcome Research Institution, London. In a footnote on the first page, Marat stated that if his essay should meet with approbation, he would offer to the public a new method of radically curing gonorrhœa in a short time!

In the text Marat described the treatment of three cases of chronic urethritis by means of suitable *bougies*, a method introduced by the Frenchman Jacques Daran (1701-84); one of Marat's patients had been unsuccessfully treated by Daran. Marat's treatment consisted in employing different *bougies* according to the stage of the infection; this seems to be an improvement on Daran's method.

The next tract was: *An Enquiry into the Nature, Cause and Cure of a Singular Disease of the Eyes, Hitherto Unknown, and Yet Common, Produced by the Use of Certain Mercurial Preparations* (London; printed for W. Nicoll—no date). This was addressed to the Royal Society, from Church Street, Soho, January 1, 1776; but its Library does not possess a copy. The only known exemplar is in the Royal Society of Medicine, London; it was discovered by the late Sir John Macalister (1856-1925) in a bundle of tracts forgotten in a basement.

In the text Marat described the treatment of three cases of inflammation of the eyes, in patients having undergone mercurial treatment and said that the condition had been confused with *gutta serena*, a term which implied failing eyesight or approaching blindness, in contrast to *gutta opaca*, or cataract with blurred vision; a medical wit said that *gutta serena* was the ailment when neither physician nor patient could see clearly. In Marat's case this diagnosis had been made by "a Fryar of some repute for curing Diseases of the Eyes". The connexion between mercurial treatment and this ophthalmia cannot be established and Marat's description of the symptoms does not allow one to recognize more than the swelling of the ocular muscles, which might influence the curvature of the lens—thus involving lack of accommodation. Marat did not know this function of the lens, though it had been mentioned in Descartes' *Dioptrica* (1637) but even Thomas Young (1773-1829) in 1792 did not give a complete description of the mechanism of accommodation.

In these cases Marat employed electric sparks to the temples, together with laxatives

and seemingly obtained considerable improvement. In the third patient Marat mentioned "a scorbutic habit" which was cured by "anti-scorbutic Remedies" such as water-cresses, bitter plants, &c. In both tracts there is no lasting contribution to the pathology or therapy of the diseases treated; it is quite believable that by persistent care and attention, Marat did obtain a definite measure of success in these cases. What is most remarkable is that no one would recognize in the obsequious, candid style of these communications, the hand of the bloodthirsty Deputy of *La Montagne* in the Convention of Paris.

Phipson in 1924 ascertained that Marat was not a householder in Church Street, Soho; the prefaces of the two tracts having been dated from there is no evidence whatever that Marat carried on a flourishing medical practice from that address, nor are the dates any proof that Marat was there at the time.

It was at this time that a remarkable incident occurred in Marat's life, no less than a theft from the Ashmolean Museum, Oxford, and his conviction to the hulks at Woolwich. All this has been denied by the majority of his biographers, but the clear evidence available will be quoted elsewhere in the near future.

What is relevant to Marat's medical career is that in May 1777 he was in Paris and called to treat the Marquise de Laubespine, who was suffering from phthisis, as a physician lately arrived from England.

A few words may be said about Mme de Laubespine, whose case is described by Cabanès, "Marat Inconnu" Paris, in Chapter VIII entitled: *Marat et les femmes*; but here we prefer to examine her case as one of pulmonary tuberculosis. That she really suffered from the disease can be accepted; five years before she had developed a dry cough, shortly after a confinement; this may well have been the flaring-up of a cryptic infection following pregnancy—a not uncommon occurrence. Notwithstanding treatment, the disease progressed, the patient lost weight, expectoration became purulent. When Marat undertook treatment, he prescribed an emulsion of almonds with salts of nitre, to which he added a secret remedy, which subsequent analysis showed to be an artificial mineral water, similar to that of Harrogate. Then followed laxatives in the shape of "*Sels de policreste*"; further, quinine extracts and Peru balsam, together with fifty drops of ambergris in a cup of cow's milk every morning. Marat does not appear to have performed percussion or auscultation, though Leopold Auenbrugger's (1722-1809) book *Inventum novum* had appeared in 1761 and had been translated into French by Rosière de la Chassagne in 1770. This useful diagnostic method had to be revived in 1808 by Jean-Nicholas Corvisart (1755-1821).

In any case in June and July of 1777 the Marquise was considered to be cured; four years afterwards she was still alive, but her subsequent life-history is unknown; her sudden improvement may well have been due to one of those remissions with temporary relief that occur in tuberculosis of the lungs. Whatever the explanation may have been, Marat's success was skillfully advertised in the *Gazette de Santé* in an article by the Abbé Filassier [? Jacques Joseph Fillassier (1745-99) author and great admirer of Rousseau]. Unfavourable critics also wrote to the *Gazette* and the Marquis de Laubespine replied, defending Marat, who also took part in the debate in December 1777.

It was Mme de Laubespine who recommended Marat to the Comte d'Artois, who then appointed Jean-Paul Marat, "a Doctor of medicine of several faculties in England" as *Médecin du Corps des Gardes* with a brevet dated June 24, 1777—which Cabanès reproduced in facsimile—pp. 104-5.

In consequence of all this, Marat was approached by several patients and entered into correspondence with others outside Paris; soon after Marat was living in an elegant apartment in the Faubourg St. Germain; his practice may well have been extensive and lucrative. How long this prosperity lasted can be approximately ascertained, because by 1783 he was trying very hard to obtain the position as head of a newly formed academy in Madrid and showed a great interest in all things Spanish. He said that his practice had suffered as the result of professional jealousy and slanders—that medicine gave him no satisfaction, when compared with the pursuit of scientific aims. He was not accepted for this post, because some French Academicians spoke and wrote against him; this is quite believable.

Next year Marat's last medical writing was published: *Mémoire sur l'électricité médicale*. Couronné le 6. Août 1783, par l'Académie Royale des Sciences, Belles Lettres & Arts de Rouen (Paris, 1784), Jorry. This is probably the best piece of work Marat did; it is mainly concerned with contesting the effects of electricity on various diseases; on p. 2 he mentioned: "... des prétendus miracles opérés par les mains des Pivati, des Verrati, des Brigoti, des Bianchi, &c." Much is also said about Abbé Bertholon, who had stated that fever was due to an excess of electricity in the blood. This was Pierre Bertholon (1742-1800) author of: *De l'électricité du corps humain dans l'état de santé et de maladie*. Ouvrage couronné par l'Académie de Lyon. Two vols. (Paris,

1786), Croulbois. Bertholon was a friend of Franklin and member of numerous academies; all the same, his medical observations are obviously superficial; moreover he had suggested preventing earthquakes by planting deep lightning conductors into the earth.

Garrison (1929), p. 327, said that electro-physiology had its origin in the epoch-making experiments on muscle-nerve preparations summarized by Luigi Galvani (1737-98) in: *De viribus electricitatis in motu musculari* (Modena, 1792). John Hunter had studied animal electricity in the torpedo fish (1773); which had been used in therapy by the Romans; Cالدani had already experimented on electrical stimulation of the cerebral cortex (1784), but Galvani's discovery of the properties of excised tissues is the starting point of modern work. On the next page Garrison wrote: "Meanwhile Benjamin Franklin (1706-90), Kratzenstein (1745), Schaeffer (1752), G. F. Roessler (electric bath, 1768), Mauduyt (1777), William Henly (1779), and many others were already utilizing electricity in the treatment of disease. Static machines were installed in the Middlessex Hospital in 1767, &c." It is therefore quite evident that Marat did not introduce therapeutic electricity, but rather denied the claims being made by others, though he reported employing electrical sparking with success in his tract on "Eyes". In this *mémoire*, Marat mentioned that in 1782 he had noted a slight improvement in the chilblains of three boys treated with electric sparks. He also referred to experiments on animals performed in October 1781 and March 1782. His conclusion was that treatment by electrical sparks or friction was useless in many diseases and in some—such as cancer or epilepsy—might even be harmful, if too violent.

Marat was dealing with a subject that was in its earliest stages and it is difficult to understand Cabanès (1911) who suggested that Marat had foreseen the use of X-rays. Such fantastic assertions are quite common in biographies of Marat.

Early in 1784 the appointment with the Count of Artois was ended, though as the result of an oversight, Marat's name continued to appear in the household list till his successor, Dr. Enguehard of Montpellier, entered the post on April 23, 1786.

This position was both lucrative and dignified; one of the physicians in the same household was Félix Vicq d'Azyr (1748-94) a renowned comparative anatomist. There was a separate veterinarian for the stables.

Once more it becomes difficult to follow Marat's movements or ascertain his means of livelihood; it has been suggested that he returned to England, opened a bookshop in Bristol and failed, being then imprisoned for debt in the name of Marat Amiat; if so he was released in December 1787 and in January 1788 was again in Paris. The evidence for the Bristol incident is contradictory but in 1788 the last scientific work of Marat was printed.

A few words will suffice for Marat's investigations of the phenomena of nervous impulses, light, fire, electricity. It has been seen that he propounded that nerves acted through a fluid with dual properties; later on he became obsessed with the theory that fire was a fluid and proved it by means of the so-called solar microscope or lenses combined with a *camera obscura*; the appearance of hot gases was so similar to that of flowing liquids; even Phlogiston was also a fluid! He then attacked Newton in relation to his observations on light; Marat held there were only three primary colours—red, blue, yellow. Electricity was also a fluid: lightning conductors were useless—here he fell foul of Benjamin Franklin. Marat accused Lavoisier of plagiarism in relation to Cavendish; some of Marat's admirers have written that he attacked Lavoisier as a *Fermier général*, not as a scientist; this is an absurd misstatement; one need only read: *Les charlatans modernes* (1791). Imprimerie Marat.

Not all contemporary notabilities ignored or opposed Marat—Lamarck and Goethe quoted him with approval.

From June 1789 onwards, Marat's activities are relatively well documented; Carlyle was wrong in saying that Marat took part in the attack on the Bastille. Marat soon developed into a fervid revolutionary journalist, voicing his bloodthirsty demands in the columns of *L'Ami du peuple*; his medical and scientific interests faded away, though he found time to print and publish in his press: *Les Charlatans modernes* (1791) in which he expressed, in no measured terms, his rage against various members of the French Academy who had refused to accept his views.

As a Deputy of *La Montagne* and a violent journalist, Marat became influential in revolutionary circles; with the help of Simonne Évrard he was able to issue his paper even when he had to go into hiding.

On July 13, 1793, a comely young woman from Caen, Charlotte Corday d'Armand, obtained an interview whilst he was immersed in his bath; after an exchange of a few words, whilst he was writing down some names, she plunged a knife into his right subclavicular space and killed him. She was arrested and after a brief trial executed the same week.

Cesare Lombroso (1835-1909) examined her skull and found it exhibiting all the characters of the prostitute-criminal type. It is not easy to be serious about many of Professor Lombroso's pronouncements, because he would have detected the same features in a turnip grown in a field belonging to Madame du Barry.

THE DIAGNOSIS OF MARAT'S DERMATOPATHIA

Since 1790—approximately—Marat had suffered from a chronic skin ailment which he said had been contracted whilst hiding underground in cellars and sewers; it was located in the groin and scrotum and was characterized by an intolerable itching, which in an irritable individual like Marat, would give rise to rabid scratching with dirty nails—so that the ailment would become worse and worse; the only relief he could find was by prolonged bathing. Cabanés (1911) concluded that it was eczema: Clifford Bax (1901) p. 131 called it *pruritus*, which can be surmised to mean *Pruritus senilis*; this occurs as the outcome of drying of the skin in old age, but since Marat was assassinated at the age of 50, the diagnosis does not seem applicable. Sir Graham Little suggested that it might have been *Dermatitis herpetiformis*, a chronic and troublesome skin disease which resists most forms of treatment. Eczema would be aggravated by prolonged immersion and the instances of *D. herpetiformis* I have seen were not localized like Marat's affection.

One of the latest authors to discuss Marat's skin disease is G.-S. Juskiéwenski—*Jean Paul Marat. Le Médecin, le Savant, le Philosophe, le Journaliste, le Révolutionnaire* (Bordeaux, 1933). This is a graduation thesis and presents the merits and defects of such lucubrations. Juskiéwenski suggests that Marat suffered from diabetes; it may be, but we have no means of deciding. The skin ailment is discussed and the learned opinion of a Professor of Dermatology is quoted; he concludes in a manner that recalls the judgment of Dr. Rondibilis. It seems to me that chronic scabies will fit origin, symptoms and localization; the intolerable itching of scabies would be alleviated by bathing. It might be objected that scabies or "*La gâle*" was well known at the time and treatment by sulphur or mercurial ointment accepted as effective. Still, Marat might well have failed in diagnosing the infestation and would not have consulted others; for at the end of the eighteenth century *Acarus scabiei* was not recognized as the cause of itch, though its parasitic nature had been described by Giovan Cosimo Bonomi (1663-96) and Diacinto Cestoni (1637-1718) in a letter to Francesco Redi; this was published in 1687, but remained unnoticed in medical circles, till 1837 when the Corsican physician, Simone Francesco Renucci demonstrated the mite in the Hôpital St. Louis, Paris. Even to-day the diagnosis is not always easy, as the result of scratch effects and for the same reason, at times, treatment is not effective. During the last war and this, I have seen in women and children instances of scabies which were not recognized under ordinary circumstances.

No doubt the skin disease influenced Marat's temperament and would account for some of his violence.

MARAT'S NECROPSY BY J.-F. LOUIS DESCHAMPS (1824)

It can be mentioned that in a letter to an unknown correspondent (ref. Vellay, 1908, p. 8) Marat refused a request to perform a necropsy; he suggested instead the name of M. Boyer, a surgeon who lived two doors away, Rue de Bourgogne. The letter began: *Ma sensibilité, mon cher Comte, ne me permettant d'assister à l'ouverture du corps d'un ami . . .*

Marat's body was examined anatomically the day after death by the surgeon-in-chief of the *Hôpital de l'Unité, ci-devant Charité*. Cabanés (1911) quoted the full protocol, from which can be gathered that Charlotte Corday's knife had penetrated the space between the first and second right ribs, transixed the lung, gone through the aorta and entered the left auricle. It is noteworthy that the whole surface of the right lung was found adherent to the pleura; so that at some time, Marat must have suffered from pleurisy. This was probably about 1788-89 when Marat made his will, because he was seriously ill.

When Corday killed Marat he was an ailing man; even so, had he survived, it is more than probable that he would have gone to the guillotine, like Robespierre, St. Just, Couthon, Hébert.

Marat was small, about five feet in height, ugly, not an impressive orator; his French pronunciation was not considered perfect; this is strange, because Neuchâtel is one of the places where good French is spoken. Many pictures of Marat are known, but only three or four can rank as accurate portraits.

WAS MARAT REALLY A PARANOIAC?

Those who believe that Marat was a madman are considering the last three or four years of his life, when many of his utterances were those of a homicidal maniac; it is also mentioned, more than once, that he suggested that if he were placed at the head

of affairs, all would be well; that he wished to become legislative and military dictator. A psychiatric diagnosis should be exact in the description of clinical, pathognomonic symptoms and take into consideration antecedents and previous behaviour of the patient. Here it can be said that the lives of father and mother, brothers and sisters of Marat have been followed and no insanity was obvious in any of them. One brother, Henri Mára, went to Russia and became a teacher in the Imperial Military Academy, under the name of Chevalier de Boudry.

Charles W. Burr—Professor of Mental Diseases, University of Pennsylvania—in: *J. P. Marat, Physician, Revolutionist, Paranoiac*, *Ann. Med. History*, 1919, 2, 248-61, justified his diagnosis thus:

"He belongs then among the insane, and is an example of paranoia of the political type. He presents the cardinal symptoms of paranoia, intense egoism, delusions of persecution, and an angry grandiosity. He has a common secondary symptom, viz., unlimited verbosity, the matter of his speeches being always the same, the wickedness of his persecutors, his own virtue, wisdom, and unselfishness. He had the paranoiac's intensity of manner in speaking, and the tremendous verbal diarrhoea which deceives the common man, who, overwhelmed by the cataract of talk, goes home feeling that the orator must be a profound thinker because he talks so well. His moral code was wrong, and yet like all paranoiacs he regarded himself as virtuous."

This discernment is thoroughly supported, but to my way of thinking, "mad" to a medical mind must mean "certifiably insane". It is true that Marat fulfilled one of the conditions for certification; he was a danger to his surroundings, for he could inflame the base passions of the populace so that they resorted to bloodshed and plunder. But it should not be forgotten that until he became cognizant of his power of swaying the mob, he behaved sanely, even if somewhat morbidly.

His egotism was not greater than that noticeable in the autobiographies of Benvenuto Cellini or Giacomo Casanova—to mention the first two names I can recall. His "delusions of persecution"—as Burr calls them—though exaggerated, were not figments of a diseased imagination; when Marat accused Frederick, Lord North (1733-92) of having attempted to suppress "*The Chains of Slavery*" it suited the Deputy of *La Montagne* to paint a dark picture of the machinations of a mouthpiece of King George III. Marat often offended those with whom he discussed scientific matters and they retorted by calling him a charlatan. In the Revolution, his enemies would have gladly taken his life, indeed they got it. His angry grandiosity—his violent verbosity—were they really exceptional or abnormal at the time? The life and behaviour of Robespierre, St. Just, Couthon, Hébert did not differ appreciably from that of *L'Ami du Peuple*. Like them, Marat developed into a sanguinary maniac when he found that by yelling: *Les aristos à la lanterne!* brought him the applause of crowds.

CONCLUDING REMARKS

Carlyle in his *French Revolution*, Vol. II, wrote: "*Prince d'Artois has withal the strangest horse-leech, a moonstruck, much enduring individual.*" It has been seen that Marat obtained a medical degree, practised mainly human medicine and as to being moonstruck or a lunatic—that is a matter of opinion. Marat was not a whole-hearted medical practitioner; he found it a convenient manner for earning a living and to pay for the printing of his philosophical works; but when his practice failed in being remunerative he preferred to revert to his researches on light, fire and electricity. It is evident that he was moderately—quite moderately—successful as a medical practitioner during two or three years in London and Edinburgh—approximately during 1774-75; the vague address "Church Street, Soho" has no real meaning. Had his practice been lucrative then he would not have settled in Paris—for his appointment with the Comte d'Artois was due to Mme de Laubespine's influence. He was very successful in Paris, 1777 to 1780-81, when it was ascertained that he lived in well-furnished apartments in the Rue Bourgogne, Faubourg St. Germain. Eventually his practice declined, as the result of professional jealousy and opposition; he soon had to live penuriously and may well have resorted to different means to make ends meet. Marat's prescriptions can be compared with those of other physicians of his time; they show him to have been a "simplicist", that is, he relied on relatively simple substances for the purpose of treatment. His success with Mme de Laubespine is explainable by the fact that instead of employing antimony, bleeding, &c. his expectant treatment gave the *vis medicatrix naturæ* a chance to improve the health of the patient.

Thus an examination of Marat's medical career allows the conclusion that neither in his methods, outlook or recorded documents, could he be considered a "quack". These abounded in London and Paris at the time; Chevalier Taylor with his florid orations, James Graham and the "Celestial Bed", Mesmer playing on his harmonika, the two Whitworth Farriers, with their "drops" and "red bottles" of medicine, "Dr." Myersbach, the urine-caster and many others besides: all these behaved quite differently from Dr. Marat, whose medical practice seems to have followed orthodox paths.

WALTER ERNEST DIXON MEMORIAL LECTURE

[Number 4]

International Biological Standards: Prospect and Retrospect

By SIR PERCIVAL HARTLEY, C.B.E., M.C., D.Sc., F.R.S.

Director of Biological Standards, Medical Research Council

SUMMARY

WALTER ERNEST DIXON was one of the first to advocate the biological standardization of drugs; he was interested in the work of the Health Organization of the League of Nations, served on its committees and gave to it freely of his time and advice. The lecture records some of the advances made, chiefly since Dixon's death in 1931, in some of the fields in which he himself had been interested and active.

The need for biological standards and units, early examples of their use, the fundamental concepts and principles introduced by Ehrlich, the effect of the First World War, the pioneer work of Madsen and Dale leading to the birth of the international idea, are described. Subsequent developments and application to a wide range of biological products, and the means adopted for bringing standards and units into use on the widest international scale are described, and the effect on research, clinical medicine, large scale manufacture and public health administration are outlined. The establishment of an international standard and unit for penicillin is dealt with in some detail, the measures taken for replenishing the stocks and preparing replacement standards are described, and the directions and applications in which future developments may be expected to occur are indicated.

To-day we honour the memory of Walter Ernest Dixon, who died fourteen years ago at the age of 60. His friends will recall his charm, his kindly friendliness, and his humour; and to them and to a wider circle he is remembered as a man of wide scientific outlook, interested throughout his life in many of the topics and biological materials we shall discuss to-day, in endocrinology and very specially in the drugs of addiction: and his services to pharmacology, which have had such an important influence on the progress of the science in England, are remembered with gratitude and appreciation. He was one of the earliest advocates of the biological standardization of drugs and his advice was frequently sought by the Health Organization of the League of Nations and he served on several of its committees. It is fitting, therefore, that we should review the progress made, in the period between the two world wars, in some of those fields of scientific activity in which Dixon himself was interested and in which he played a part.

There are a number of substances in common use in medicine the activity of which cannot be estimated by the usual chemical or physical means and for which, accordingly, other methods have had to be devised for the determination of their potency. Many of the more important of these are shown in the table. They are mainly of biological origin and, when first introduced to the laboratory worker or the doctor, they were crude products, mixed up with other substances of equal or greater complexity, devoid of characteristic chemical or physical properties by which they might be identified or characterized and, perhaps, assayed. The usual basis of dosage, by weight or volume, is clearly inapplicable to substances such as these and yet, in the case of many of them, it is obviously very important that the quantity being administered should be known and capable of being adjusted to the needs of the individual patient. The solution to this problem which science has devised is to define their potency in units of biological activity and it is one of the practical aims of biological standardization to provide, for the use of the doctor and the research worker, preparations of which the potency has been accurately determined and expressed in a common system of unit notation and completely accepted.

INTERNATIONAL BIOLOGICAL STANDARDS.

Standard preparation	First adopted	International unit mg.	International distributing centre
Diphtheria antitoxin	1922	0.0028	State Serum Institute, Copenhagen
Tetanus antitoxin	1928	0.1547	
Antidysentery serum (Shiga)	1928	0.0500	
Staphylococcus antitoxin	1934	0.5000	
Antipneumococcus serum (Type 1)	1934	0.0886	
Antipneumococcus serum (Type 2)	1934	0.0894	
Gas gangrene antitoxin (perfringens)	1931	0.2660	
Gas gangrene antitoxin (Vibrio Septique)	1934	0.2377	
Gas gangrene antitoxin (oedematis)	1934	0.2681	
Gas gangrene antitoxin (histolyticus)	1935	0.3575	
Gas gangrene antitoxin (sordelli)	1939	0.1334	
Old tuberculin	1931	—	
Diphtheria antitoxin for the flocculation test	1935	—	
Vitamin A (mixed carotenes)	1931	0.001	National Institute for Medical Research, Hampstead, London
(pure β -carotene)	1934	0.0006	
Vitamin B ₁ (adsorption product)	1931	10.0	
(pure synthetic vitamin B ₁)	1938	0.003	
Vitamin C (<i>L</i> -ascorbic acid)	1934	0.05	
Vitamin D (irradiated ergosterol soln.)	1931	1.0	
(calciferol)	1934	0.000025	
Vitamin E (α -tocopheryl acetate)	1941	1.0	
Arsphenamine	1925	—	
Neoarsphenamine	1925	—	
Sulpharsphenamine	1925	—	
Insulin (crude dry hydrochloride)	1925	0.125	
(pure crystalline)	1935	0.0455	
Pituitary (posterior lobe) powder	1925	0.5	
Digitalis	1925	80.0	
Ouabain	1928	—	
Oestrus-producing hormones :			
(1) Oestrone	1932	0.0001	
(2) Oestradiol monobenzoate	1935	0.0001	
Androsterone (for male hormone)	1935	0.1	
Corpus luteum hormone (progesterone)	1935	1.0	
Chorionic gonadotrophin	1938	0.1	
Serum gonadotrophin	1938	0.25	
Thyrotrophin	1938	—	
Prolactin (galactin or mammatrophin)	1938	0.1	
Heparin	1942	0.0077	
Penicillin	1944	0.0006	

Even in their crudest form these substances exhibit specific biological properties, often unique and quite characteristic, which can be demonstrated by means of animals; and it is these characteristic biological reactions which man has exploited and applied and made to serve as a basis for the determination of their potency. Thus, given two samples of one of these substances, then their relative potency can be estimated by determining how much of each is required to produce the same biological effect: or, if one of these two is taken as the "standard" it is possible to find out how much of any other sample produces the same biological effect as 1 milligramme, or 1 microgramme, or 1 unit of this standard. If the total amount of the standard is sufficiently large, quantities of it can be sent to any laboratory in the world and the potency of substances can be determined in relation to this common standard and expressed in a common system of unit notation. The one essential condition for the successful performance of these potency determinations is that the biological tests upon which they are based shall be carried out under strictly comparable conditions.

The therapeutic substances for which international biological standards have been established and adopted form a very varied group, and their origin and purpose are likewise very diverse. Most of them are of relatively recent discovery, all of them are substances of great biological interest and importance. In so far as they are used in medicine the point immediately emerges that they are not mere palliatives, used for the alleviation of symptoms, but they are specific remedies for the prevention or treatment of disease, or for the replacing of defects or deficiencies from which the human body may be suffering. Some of these substances are potentially dangerous and for their safe and effective use they must be administered by precise dosage. The need for precise measurement is no less great for the research worker in the fields in which these materials are studied or used. Without a common standard, a common basis of measurement and a common

system of notation the results of investigations in different laboratories and hospitals in different countries cannot be correlated and compared.

Expressed in its simplest form, a biological standard may be defined as an arbitrarily chosen but representative sample of the substance for which it is to serve as a basis of measurement, preserved under conditions ensuring its permanence; and, in general terms, a unit may be defined as the specific biological activity contained in a certain weight of such a standard.

The individual laboratory worker, if he chooses, can establish a standard and unit for himself in order that the measurements he may be making at different times can be correlated and compared. The currency of such a standard and unit may extend no further than his own laboratory, unless, of course, a few workers studying the same problems and using the same or similar materials may wish to have a common basis of measurement and then this currency is extended accordingly.

Similarly it might be desirable that all batches, or types or makes of a commodity or drug supplied in a particular country, should conform to certain requirements and it is then proper to establish a standard, and if need be a unit, which would have a national currency and serve the needs and convenience of workers within a national boundary, thus ensuring that statutory requirements are everywhere complied with in that country.

International standards and units are intended to have the highest authority, to be operative on a world scale and enjoy the widest possible currency: and obviously there must be some representative body, properly constituted and having authority, whose decisions and edicts carry weight and are respected if these objects are to be achieved.

Such a body is the Permanent Commission on Biological Standardization of the Health Organization of the League of Nations which was established in 1924. The Commission has had two main objects: (1) To create, establish and provide standards by means of which the potency of certain biological products can be determined and expressed in a uniform system of unit notation; and (2) to secure the acceptance of these standards and units for international use on the widest possible basis.

EARLY ATTEMPTS AT BIOLOGICAL STANDARDIZATION

Looking back from the vantage ground of the solid achievement represented by these thirty-five material standards it is interesting to examine the origins and trace the development of the ideas and the work which led to their creation, to the world-wide interest they have since aroused, and to their extensive application to serve the needs of modern medicine and research. The history of biological standards began half a century ago when physicians using the new diphtheria antitoxin, the discovery of which had been announced by Behring in 1890, found that their clinical studies were seriously handicapped because they were so uncertain about the potency of the antitoxins they were using. Roux and his colleagues, whose communication to the International Congress of Hygiene at Budapest in 1894 reporting the clinical efficacy of diphtheria antitoxin created such a deep impression, attempted with little success to determine potency by a complicated method in which the weight of the animal, the dose of antitoxin given and the time of survival following the injection of living culture all had to be taken into account; and while the early attempts of Behring and the German workers, based on determining the amount of antitoxin which neutralized a certain number of so-called "minimum lethal doses" of toxin was simpler, these like the French attempts, failed because the highly complex nature of diphtheria toxin was not then understood. An appeal was made to Ehrlich, not specially interested at that time in problems of this kind and not yet the world-famous figure which he subsequently became, who was thus led to a series of investigations which not only solved these immediate problems of antitoxin standardization but laid the foundations of what has properly come to be recognized as the modern science of biological standardization. Ehrlich revealed the complexity of diphtheria toxin and explored its various reactions with antitoxin; and his discovery that "toxins" contained in variable amount a substance which, though without toxic action, nevertheless neutralized antitoxin provided an explanation for Behring's bewilderment and failures. As a result of these investigations Ehrlich showed that the only way out of the maze and the difficulties was to adopt a sample of diphtheria antitoxin as a "standard" in comparison with which the potency of other samples of diphtheria antitoxin could be determined; and he also showed that the unit of diphtheria antitoxin was properly defined in terms of this standard, viz. as the specific biological activity (in this case the neutralizing or combining power for diphtheria toxin) contained in a given quantity of the standard—two important fundamental principles; and he passed to a third. He recognized that, since the unit must be a fixed unvarying quantity, it was essential that the standard must also be fixed and stable. Accordingly, since liquid preparations of antitoxin lose their potency slowly with age, Ehrlich reduced the sample of diphtheria antitoxin selected for the standard to the absolutely dry condition and preserved it constantly at low temperatures *in vacuo*.

THE FIRST STANDARDS FOR DIPHTHERIA AND TETANUS ANTITOXINS

This first important standard, for diphtheria antitoxin, was supplied from Ehrlich's Institute at Frankfurt to laboratories all over the world and, although French workers dissented on some points, the great majority of other workers supported Ehrlich's views and confirmed his results; and order and uniformity were introduced into the standardization of diphtheria antitoxin.

In 1905, another and separate standard for diphtheria antitoxin was established at the Hygienic Laboratory at Washington (as this Institute was then known) and the unit of diphtheria antitoxin which Ehrlich had established was defined as a weight of this standard also—an important and fortunate circumstance in the light of subsequent events. Moreover, this work at Frankfurt and Washington had proved so successful in regard to the assay of diphtheria antitoxin that, in both these countries, dry stable standards were established for tetanus antitoxin. At Frankfurt the assay of tetanus antitoxin, in relation to the standard, was on somewhat different lines from those adopted at Washington. The Hygienic Laboratory, indeed, followed the original methods which Ehrlich had applied with such success to diphtheria antitoxin very closely, and the result was that the American standard and unit for tetanus antitoxin were well established and in common use, particularly in the laboratories of the United States and of this country, for some years before the outbreak of war in 1914—another fortunate circumstance.

THE BEGINNINGS OF INTERNATIONAL CO-OPERATION

With the outbreak of war in 1914, the supply of the diphtheria antitoxin standard from Frankfurt ceased at once; and the sudden removal of this essential reagent was one of the facts which led, first, to the establishment of the standard for diphtheria antitoxin on an international basis and, secondly, to the creation and adoption of international standards for other substances. In 1921, thanks to the initiative of Dr. Thorwald Madsen, Director of the State Serum Institute at Copenhagen, an international conference was held in London, under the auspices of the Health Organization of the League of Nations. The immediate purpose of this conference was to ascertain whether the unit for diphtheria antitoxin, based on the standard established at Washington, which had been used in different parts of the world during the war, differed from the original unit established by Ehrlich and maintained at Frankfurt. It was found that no change in the unit value had occurred and the conference recommended the adoption of this original unit of Ehrlich as the international unit. This was an event of great importance to science and medicine; but of even greater significance was the fact that, so shortly after their countries had been at war, men of science could meet together for the pursuit of the common aim of extending our knowledge and promoting the benefit of all mankind. Madsen was a great figure in international science; his country had not been at war and it is to his everlasting credit that he saw this opportunity and seized it so promptly, with such happy and fruitful results.

In the following year a second international conference met in Paris to explore the possibility of establishing standards and units for other antitoxins and antisera. The success of these two conferences led to what we now recognize as a most important milestone—the extension of this international enterprise to substances other than antitoxins but which, like them, could only be standardized by biological methods. During a visit to England in 1922 Madsen, whose major interest was serology and immunology, suggested to Sir Henry Dale that something on similar lines might be done for other substances. The heart drugs, extracts of the posterior lobe of the pituitary body, the arsphenamines (for which during the war Dale himself had devised biological tests for their control) and insulin all presented problems similar to those which had arisen in the case of antitoxins and, as fortunately proved to be the case, capable of solution on similar lines. The outcome of all this was that an international conference was held at Edinburgh in 1923 followed by one in Geneva in 1925, Dale being chairman on both occasions, at which international standards for digitalis, pituitary (posterior lobe) extract, insulin and the arsphenamines were agreed upon and adopted.

THE PERMANENT COMMISSION ON BIOLOGICAL STANDARDIZATION

The marked success of these early conferences led to the formal institution in 1924 by the Health Organization of the League of Nations of the Permanent Commission on Biological Standardization. This was a small body of experts chosen for their scientific qualifications and attainments, all interested in some aspect of biological standardization, and regardless of whether their countries belonged to the League or not. Dr. Madsen has always been the Chairman of this Commission and, right from the beginning, Sir Henry Dale has been the sole representative of this country on the Commission and, indeed, almost the sole representative for the biological standards for drugs, vitamins and hormones. The other members of the Commission were experts from France, Belgium, Germany and the United States. The personnel was enlarged somewhat in 1935.

The international standards for the antitoxins, antisera and for tuberculin are maintained at the State Serum Institute at Copenhagen, while the international standards for all other substances—insulin, pituitary extract, the arsphenamines, the vitamins, the sex hormones, the heart drugs, heparin and penicillin—are maintained at the National Institute for Medical Research at Hampstead. From these two international distributing centres the standards are supplied to laboratories, institutes and research workers throughout the world; and by thus providing a common basis of measurement and a uniform system of nomenclature and unit notation, the results of research, whether in the laboratory, the hospital or the field and in whatever country, can be correlated and compared. The

use of the same standards and units are of no less importance to the manufacturer who can compare his products with those made in any other laboratory and provide them for use in any other country; their adoption has greatly facilitated the international exchange of these substances whether for the treatment or prevention of disease or for purposes of research. The practical advantages and benefits of a universally acknowledged and accepted system of standards and units are greatest, perhaps, in clinical medicine; by their use the authenticity, potency and quality of these important therapeutic substances are controlled and, very largely, guaranteed; and doctors and patients can obtain, for their use in other lands, drugs and remedies, such as insulin, for example, which are as reliable as those which they have been accustomed to use in their own country.

The Commission has had a twofold purpose—first, to provide international standards and units as and when they are required and, secondly, to secure their adoption and effective application on a wide international basis. It is not always easy to decide whether a standard should be established at a particular time; if action is taken prematurely an unsuitable standard or a unit of unsuitable size may be adopted, while if action is unduly delayed there is the opposite danger that a multitude of different units which may be quite unrelated or impracticable may be proposed, brought into local or national use, defended by a powerful advocacy or a stubborn persistence and withdrawn or modified with reluctance. On the whole the Commission, partly by judicious choice of the appropriate moment to take action and partly by the display of a wide toleration and a wise compromise, has been remarkably successful in securing agreement in essentials. When delegates meet in conference important factors such as the suitability and availability of the material to be used as a standard, whether there are methods of assay available and the order of accuracy of their application, the merits of rival claims for a standard or unit, and other such matters appear in their due perspective and are discussed in their proper relation to the main points at issue; and in the end, by inquiry, investigation, discussion and conference, added to and aided by the co-ordinated research in many countries and many laboratories which has been carried out, chiefly by the delegates themselves prior to the Conference, agreement is reached. Only once has there been serious disagreement, and as this occurred early in the development of this work and the consequences have been so disastrous, it may be that this single failure to achieve agreement (concerning the unit of tetanus antitoxin) served as a warning for the future.

INTERNATIONAL UNITS

A unit is properly defined as the specific biological activity contained in a given weight of the standard preparation; and, in the table, in regard to 28 of these 35 substances, the weight of the respective international standard which has been accepted as the international unit is recorded. It will be noticed that these weights vary from a fraction of a microgramme to as much as a milligramme, and, in the case of digitalis, to the large value of 80 milligrammes.

The size of the international unit has been arrived at in different ways. Sometimes a unit which has become established through common usage, as in the case of diphtheria antitoxin and penicillin, has been recommended for adoption by the Commission; and sometimes an arbitrarily chosen weight of the standard is adopted as in the case of antidyentery serum and staphylococcus antitoxin. Frequently, however, the size of the unit recommended for adoption is either the result of compromise between conflicting claims, or (and perhaps more commonly) it results indirectly from the Commission's successful substitution of sound principle for fallacious reasoning and argument. Thanks to a generation of sound teaching and effective advocacy, it is now becoming more generally recognized that potency cannot be determined, and units of activity cannot be defined, by simple observation of the effects produced on an animal, or, as it is expressed, in terms of an animal reaction; that this is because of the wide variation in animal response to the same biological stimulus; that this factor of animal variation, more than any other, dominates the whole field of biological standardization, and that it can only be controlled and allowed for by the adoption of standard preparations and by carrying out the biological tests on the standard and the sample of unknown potency under strictly comparable conditions. In the past, it was only too common to find that, when a substance with biological activity and possibly clinical application was discovered, a unit of activity was proposed which was defined as the quantity which produced a certain biological effect. Thus, it was proposed that the unit of insulin should be defined as the quantity which reduced the blood sugar of a rabbit to a certain low level, the unit of a vitamin as the quantity which restored growth, and so on. A very few experiments showed that these quantities were very far from being constant; they varied in different laboratories, from one animal to another and from day to day in the same laboratory. Now, very often the size of an international unit bears some rough and approximate relationship to the biological effect it produces; for example, the unit of insulin is a quantity which reduces the blood sugar of many fasting 2 kilogram rabbits to the convulsion level, but it does not produce this effect with all rabbits, and not always with the same rabbit, and not with

regularity. In conferences called by the Commission to decide about standards and units, it has frequently been possible to get those who rightly believed that the unit should be a weight and those who wrongly believed that it should be an animal reaction to reach agreement by fixing the unit at, or about, the weight which usually produced the particular biological reaction which, to some of the delegates, appeared to be the kernel of the matter. But from all these discussions and conferences the final definition of the unit recommended for adoption is always the same, viz. the activity contained in a certain weight of the standard and, as the standard is a dry stable substance, so also is the unit fixed, definite and unchanging.

One consequence of this desire to reach agreement in regard to units of activity has been that the size of the unit adopted for international use has not always been the most practicable and best suited to the needs of medicine; occasionally the unit adopted has been so small that the dose of the drug administered to patients has reached astronomical figures. Many factors, known and appreciated better perhaps by a body like the Commission than by an individual laboratory worker or physician, enter into the question as to what constitutes a suitable unit; and it would be an advantage, in the future, if questions relating to the unit could be left to a body with experience like the Permanent Standards Commission.

PREPARATION AND PROPERTIES OF BIOLOGICAL STANDARDS

One essential of a biological standard is that it shall be stable, and this requirement is met by preparing it in the absolutely dry condition and preserving it constantly at low temperatures, in sealed containers, in the absence of light, moisture and oxygen. Although the materials for these standards have come from many countries, the final operations to secure these conditions of permanency and stability for twenty-eight of them have been carried out in England and, for twenty-four of these, at Hampstead during the past twenty years. Ways and means have had to be devised, varying with the particular standard but appropriate to each, for providing these conditions for ensuring stability. When this work was begun at Hampstead over twenty years ago there was little more than the experience and teaching of Ehrlich to go upon, but it seemed reasonable to expect that if the possibilities and opportunities for chemical and physical change were reduced to the lowest attainable minimum, then the standards should undergo no change. It may now be claimed with some confidence that these expectations have been realized.

Except in the case of tuberculin the basic standard is a dry preparation, and each standard is dispensed so that it is readily accessible and capable of being brought into use with a minimum of trouble, extra manipulation and delay. Since world needs are to be met, and for long periods, the quantity set aside for use as an international standard must obviously be very large, and the stocks held at Hampstead at present are adequate for world needs for very many years.

Five of the original international serum standards were made at Hampstead and a number of equivalent national standards have had to be made for the purpose of the British Therapeutic Substances Act and the British Pharmacopœia; and during the war replacement standards, on the international account, for perfringens, septicum and œdematients antitoxins had to be prepared.

A method for preparing serum standards was devised in 1923 (Hartley, 1935) and has been widely used in many laboratories since that time.

By this method a very large number (several hundreds) of sealed ampoules, each containing the same weight of standard antitoxin in the dry stable condition, is obtained and it is only necessary to determine, once and for all, the number of units present in an ampoule, and the preparation of the usual standard solution is then made as required and distributed to laboratories all over the world.

This is a very simple method: the different stages are easily controlled, sterility is maintained without any difficulty, and only ordinary laboratory apparatus is required. The final product is very stable. The defects of the method are that it takes several weeks to complete the operations and, although there is no loss of potency during drying, the final product dissolves rather slowly. These are defects which will be overcome in the future by drying from the frozen state by one of the methods which have been devised and used during the war. Further, it is quite practicable to prepare standards for substances other than antitoxins by making solutions of them, distributing precise volumes into ampoules, and drying them from the frozen state.

The International Sources of the Materials for the Standards

To illustrate the international character of this work it may be stated that the material for the serological standards has been supplied from Denmark, England, France and the United States; the tuberculin standard was made in England; material for the vitamin standards came from Switzerland, the Netherlands East Indies, Hungary, England, France, Germany, Sweden and the United States; that for the arspenamines was provided originally from Germany and the United States and, since 1935, from England; the first insulin standard was made in England, the second in Canada; the material for both of the pituitary (posterior lobe) standards was supplied from the United States and manipulated into a standard in England; the first digitalis standard was prepared in Holland, the second in England; the ouabain standard was supplied from France. The materials for the sex hormone standards, some of them rare and costly, were supplied from England, France, Germany, Holland, Denmark, Sweden, Switzerland and the United States. Canada provided the material for the heparin standard, and the United States and this country that for the penicillin standard. It is very gratifying to record, and may be taken as evidence of the esteem in which this work is held, that practically all the material for these standards has been presented to the international organization, and some of these gifts represent very large sums of money. A laboratory in Switzerland presented 30 grammes of androsterone to provide the material for the replacement of the standard for male hormone activity; one laboratory in England presented 20 grammes of the purest Beta-carotene to provide the material for the replacement of the standard for vitamin A, and another has presented 30 grammes of the sodium salt of pure crystalline penicillin II for the use of the Department of Biological Standards at Hampstead. The League, on its part, makes no charge whatever, neither to countries nor to individuals, for the supply of the international standards. And it may be added that free distribution is the invariable rule for all standards issued from Hampstead on a National basis, or to, the British Commonwealth of Nations or to individual research workers. Whatever changes the future may hold, it is to be hoped that this free distribution of biological standards will be everywhere maintained.

The Establishment of Standards and Their International Distribution

Brief reference will be made to the course of events which led to the adoption of international standards for the vitamins and to the subsequent developments in this field as this will serve as a particular instance to illustrate the procedures followed by the Permanent Standards Commission which have been outlined in general terms, first for the establishment of standards and, secondly, for securing their widespread acceptance and application.

The main decisions were reached at two international conferences held in London, the first in 1931 and the second in 1934, Sir Edward Mellanby being Chairman on both occasions.

Prior to the first conference a number of laboratories in several countries were becoming concerned about the assays of the vitamins B₁ and D. As on other occasions there was much and increasing confusion because of the multiplicity of units—pigeon units, rat units, guinea-pig units and so on—which had been proposed, all based on animal reaction, all unsound in principle and all impossible of wide-scale application in practice. Actually one of the first tasks at that first conference, as on so many other occasions, was to convince all the delegates that the only way to solve these problems was to adopt stable standards and define units in terms of them. Having before it the results of the examination of a sample of carotene prepared in England, a preparation of Vitamin B prepared in Java, and a sample of irradiated ergosterol prepared in England the first conference had no difficulty in recommending the adoption of these as provisional standards for a term of years for the vitamins A, B₁ and D and of defining units in terms of them.

Certain other investigations were planned and other materials were examined later, so that at the second international conference held in 1934 pure Beta-carotene was adopted as the standard for vitamin A, the adsorbate on fuller's earth was continued for that for vitamin B₁, ascorbic acid that for vitamin C and calciferol as the basic standard for vitamin D. A third international conference, also to be held in London, was planned for 1939, but had to be abandoned and some of the more important and urgent matters have had to be settled in other ways.

Although it is not included in the table, it should be mentioned that all the first international conference was able to recommend for use as a standard, in 1931, for vitamin C, was the juice of a lemon, the unit recommended being 0.1 c.c. But even this was better than nothing and better than a unit defined in terms of an animal reaction because, in less than three years, ascorbic acid had been discovered, its identity with vitamin C established and its synthesis achieved. There was no difficulty about adopting ascorbic acid as a stable standard for vitamin C and the international unit was actually determined in relation to this first crude vitamin C preparation.

regularity. In conferences called by the Commission to decide about standards and units, it has frequently been possible to get those who rightly believed that the unit should be a weight and those who wrongly believed that it should be an animal reaction to reach agreement by fixing the unit at, or about, the weight which usually produced the particular biological reaction which, to some of the delegates, appeared to be the kernel of the matter. But from all these discussions and conferences the final definition of the unit recommended for adoption is always the same, viz. the activity contained in a certain weight of the standard and, as the standard is a dry stable substance, so also is the unit fixed, definite and unchanging.

One consequence of this desire to reach agreement in regard to units of activity has been that the size of the unit adopted for international use has not always been the most practicable and best suited to the needs of medicine; occasionally the unit adopted has been so small that the dose of the drug administered to patients has reached astronomical figures. Many factors, known and appreciated better perhaps by a body like the Commission than by an individual laboratory worker or physician, enter into the question as to what constitutes a suitable unit; and it would be an advantage, in the future, if questions relating to the unit could be left to a body with experience like the Permanent Standards Commission.

PREPARATION AND PROPERTIES OF BIOLOGICAL STANDARDS

One essential of a biological standard is that it shall be stable, and this requirement is met by preparing it in the absolutely dry condition and preserving it constantly at low temperatures, in sealed containers, in the absence of light, moisture and oxygen. Although the materials for these standards have come from many countries, the final operations to secure these conditions of permanency and stability for twenty-eight of them have been carried out in England and, for twenty-four of these, at Hampstead during the past twenty years. Ways and means have had to be devised, varying with the particular standard but appropriate to each, for providing these conditions for ensuring stability. When this work was begun at Hampstead over twenty years ago there was little more than the experience and teaching of Ehrlich to go upon, but it seemed reasonable to expect that if the possibilities and opportunities for chemical and physical change were reduced to the lowest attainable minimum, then the standards should undergo no change. It may now be claimed with some confidence that these expectations have been realized.

Except in the case of tuberculin the basic standard is a dry preparation, and each standard is dispensed so that it is readily accessible and capable of being brought into use with a minimum of trouble, extra manipulation and delay. Since world needs are to be met, and for long periods, the quantity set aside for use as an international standard must obviously be very large, and the stocks held at Hampstead at present are adequate for world needs for very many years.

Five of the original international serum standards were made at Hampstead and a number of equivalent national standards have had to be made for the purpose of the British Therapeutic Substances Act and the British Pharmacopœia; and during the war replacement standards, on the international account, for perfringens, septicum and œdematians antitoxins had to be prepared.

A method for preparing serum standards was devised in 1923 (Hartley, 1935) and has been widely used in many laboratories since that time.

By this method a very large number (several hundreds) of sealed ampoules, each containing the same weight of standard antitoxin in the dry stable condition, is obtained and it is only necessary to determine, once and for all, the number of units present in an ampoule, and the preparation of the usual standard solution is then made as required and distributed to laboratories all over the world.

This is a very simple method: the different stages are easily controlled, sterility is maintained without any difficulty, and only ordinary laboratory apparatus is required. The final product is very stable. The defects of the method are that it takes several weeks to complete the operations and, although there is no loss of potency during drying, the final product dissolves rather slowly. These are defects which will be overcome in the future by drying from the frozen state by one of the methods which have been devised and used during the war. Further, it is quite practicable to prepare standards for substances other than antitoxins by making solutions of them, distributing precise volumes into ampoules, and drying them from the frozen state.

The actual international standard preparations obviously cannot be used for the routine assays of penicillin as the total quantity available is far too small; they are supplied for the assay and periodical check of equivalent national standards which the national control centre of each country is, quite properly, expected to prepare. The national control centre will then supply its national standard, exactly assayed in terms of the international standard, to all those laboratories requiring it in its own country and, with this, each laboratory will assay, and check periodically, its day-to-day working standard.

The first preparation used for providing a means of assaying the activity of penicillin samples prepared in different laboratories was supplied by Florey and his colleagues from Oxford and the unit of activity, which came to be known as the Oxford Unit, was defined as the activity contained in 0.23 milligramme of this first preparation. It was supplied to workers in this country and in the United States and, one way and another, this original Oxford Unit was re-defined in many other more active preparations. For the purpose of establishing a standard for use in connexion with the British Therapeutic Substances Act, the Hampstead Institute was provided with two such accurately assayed preparations, one of which contained 71 and the other 84 units per milligramme. With these the potency of the British standard for penicillin was determined with the greatest possible precision. These three English penicillins and two accurately assayed preparations from the United States, which conveyed the American version of the original Oxford unit, were included in the samples examined for the London Conference. Three most interesting conclusions emerged from the results of the comparative tests carried out, in this country and in North America, on these samples. First, the results of the assays showed remarkably good agreement despite the different methods employed by the collaborators. Second, there was good evidence that the value of the unit being used was the same in the United States as in this country, from which it certainly seems that, despite the repeated re-definition of the unit in both countries, the original value of the unit as defined at Oxford had not been significantly varied in its value in either country—a very remarkable result. Third, the conference pointed out that the value of the unit recommended for international use was approximately equivalent to that originally adopted at Oxford. The wheel had thus come full circle; just as the unit established by Ehrlich for diphtheria antitoxin was afterwards adopted as the international unit so here, too, international status has been accorded to a unit which had its origin in the laboratory where so much had been done, in those early difficult times, to bring the fruits of Fleming's great discovery within the reach of all.

International Biological Standards in the Service of Medicine

Another circumstance which has contributed towards a wide distribution of the international biological standards is the recognition of the important part they play in ensuring the high quality of the therapeutic substances provided for use in medicine, for which they serve as standards. This may be illustrated by reference to British practice and experience.

For nearly twenty years the supply of certain drugs and medicaments in this country has been controlled by means of the Therapeutic Substances Act. In general terms these materials are described as "Substances the purity and potency of which cannot be adequately tested by chemical means"; and many of the most important of them—the anti-toxins and tuberculin; insulin, pituitary extract and the arsphenamines—are listed in the table, and for all of them international standards have been established. Stated quite simply, the Therapeutic Substances Act requires that the potency of the substances controlled by it shall be expressed in terms of the international standards and units, and in no other. But this Act, excellent and effective as it has proved to be, is limited in scope and in its geographical application. Its control does not extend to the vitamins nor the heart drugs for example, and the sphere of its application does not extend beyond Great Britain and Northern Ireland. A way has been found, however, whereby both of these limitations may be overcome and many of the undoubted benefits and advantages of the Act made to operate in a wider field. This has been done by bringing the substances for which international biological standards have been established within the scope of the British Pharmacopœia; and the Pharmacopœia, on its part, has laid down the principle that the standards and units to which pharmacopœial preparations must conform are the international biological standards and units.

In many parts of the British Commonwealth and Empire, in Canada, South Africa and in India, for example, a control over these substances similar to our own has been established, and in these countries also the international standards are in general use. In other parts of the Commonwealth and Empire matters have not yet advanced so far; but, in many of these countries, the British Pharmacopœia has statutory authority, and

Experience at Hampstead has shown that it is one thing to make a standard, assay it, dispense it and get it accepted by the League; it is quite another problem to get it brought into use on a wide international scale. Quite early in this work it was noticed that the standards which had been adopted and were available were not being asked for and were not reaching the laboratories of the world. They looked like becoming museum specimens. In order to ensure that the vitamin standards reached the laboratories where they were required and, it may be added, in order to simplify the administrative problems at Hampstead, countries were invited to nominate national distributing centres and to indicate how many laboratories in each country required each of the vitamin standards. Twenty-three countries did so, and these received the very large supplies they required at once, and these were easily replenished as required. Nine countries failed to nominate national distributing centres and it was actually found that hardly any of the standards reached these countries. So, successful had this scheme been with the vitamin standards that, later in 1935, at an intergovernmental conference at Geneva, it was extended to all other standards and all other countries, and by the spring of 1939 thirty-five countries had made a start with the establishment of a national control centre to deal with standards. One important consequence was that in the early months of 1939, before the outbreak of war in September, there was no difficulty in sending large consignments of the international biological standards provided from Hampstead to all those thirty-five countries and in this way the threatened shortage of these essential materials was largely averted. But this care and distribution of the international standards was only a beginning of the work of these national control centres: it was hoped and intended that many countries would establish and maintain such a centre and thus arouse an interest in this field and stimulate research into the varied problems which are continually arising in regard to the standards and the methods of their application.

This aspect of the problem of international standards has been described in some detail because experience of this work at Hampstead has clearly shown that the establishment of national control centres has been the means of securing a wide international recognition, distribution and application of the standards, and it has aroused a real and active interest in places which might otherwise have remained uninformed and passive in standards, units and assay. The policy of international co-operation on the widest possible basis should be adopted and extended in any further schemes which may be established for the continuation of this work.

The International Standard and Unit for Penicillin

The establishment of the first biological standard by Ehrlich has been described and it may be appropriate to say something of the latest standard—what in fact may prove to be the last standard—established by the Permanent Commission on Biological Standardization, viz. the international standard for penicillin. This provides another illustration of the way the Permanent Standards Commission has approached its problems and attained its objects.

For many reasons it was desirable that an international standard and unit for penicillin should be agreed to and established without delay, so that a unit of penicillin would always mean the same thing, not only at the present time when all this work is being pursued by highly skilled experts in a few countries, but in the future when penicillin comes to be made by others, not so expert, in other countries. It is a remarkable fact that, even in wartime when transport and the circumstances of our daily life were as difficult as they well could be and everybody was very busy, it was possible for the Permanent Standards Commission to fulfil its traditional rôle, at any rate in essentials and even if in a somewhat restricted manner, by bringing together experts on penicillin into conference to advise and decide on these important matters. Delegates from the United States and Canada, from France, Great Britain, and Australia, and expert observers from all these countries and from India and South Africa, met at the Royal Society's rooms in October 1944 under the chairmanship of Sir Henry Dale. After the consideration of certain assay data provided by those attending the conference and of other relevant matters concerning nomenclature, standards, units and methods of assay, the conference unanimously recommended the adoption of a sample of pure sodium salt of penicillin II as the international standard; and, for practical reasons which were certainly justified at that time, the adoption of a sample of a calcium salt of penicillin as the international working standard. The international unit was defined as the specific penicillin activity contained in 0.6 microgramme of the international standard and an international unit is contained in 2.7 microgrammes of the international working standard. The conference recorded other decisions relating to nomenclature, how the material for the standard was to be acquired, finally prepared and dispensed; and directed that the standards should be held by the Department of Biological Standards at the National Institute for Medical Research, Hampstead, on behalf of the Permanent Standards Commission of the Health Organization of the League of Nations and supplied therefrom to all requiring them throughout the world.

standard; and then it is necessary to ensure that the new sample is assayed with the greatest possible precision in terms of the original standard so that the value of the unit is maintained at its exact international value. It is the invariable practice to enlist the co-operation of such experts in this and other countries as are available and willing to carry out these fundamentally important comparative assays.

These replacement operations have provided the opportunity for international co-operation both in scientific research and in the application of its results to the practice of medicine. The first insulin standard was prepared at Hampstead by Dudley and the international unit for insulin was then fixed for all time and defined as the specific insulin activity contained in one-eighth of a milligramme of the standard. This first standard lasted for ten years, but towards the end of its currency period it had come to be questioned whether it could still be accepted as a representative sample because manufacturers were then preparing much purer insulins, containing over twenty units per milligramme, and these differences in quality occasionally showed up in the comparative assays for potency. So in this case replacement became necessary on the dual grounds of exhaustion of the stocks of the first standard and its qualitative disparity from the insulins of commerce. The work of Abel and Scott made it possible to replace this first, rather crude, international insulin standard by an adequate quantity of pure crystalline insulin and the unit value of this was determined with great precision in many laboratories in Europe and America, and it was finally agreed that this value was 22 international units per milligramme.

The replacement of the first international standard for pituitary (posterior lobe) extract presented peculiar difficulties but, at the same time, intriguing scientific problems. This standard is unique in the sense that the international unit is an optimal, rather than a fixed arbitrary value, and there was no doubt that when the new and old standard preparations were compared the new was some 12% more potent than the old. It will probably never be known whether this discrepancy was due to the adoption of a superior technique for the preparation of the replacement standard, whereby a more efficient dissection of the gland, better refrigeration and quicker working gave a final product which actually yielded that maximum activity which it was intended, and expected, all such preparations would give; or whether the original standard during the fourteen years of its currency had lost potency to the extent of about 1% per annum. This instance is mentioned because, apart from its technical interest and its importance to the whole work of biological standardization, the difference was revealed as a result of co-ordinated comparative tests carried out in thirteen laboratories in five different countries. The consequences of these findings and the alternative procedures for action which could be taken were discussed and settled by international action and a solution of the difficulty, satisfactory to all countries and all interests concerned, was reached.

The original standard for vitamin B₁ was an adsorption product of the active material on fuller's earth and the international unit was defined as the specific activity contained in 10 milligrammes. For seven years this standard served for the assay of vitamin B₁, but during all this time purer preparations of the vitamin were being made and tested against this first crude standard until, finally, the pure synthetic aneurin hydrochloride emerged and was found to contain 330 units per milligramme. Thus, while the unit for vitamin B₁ remains unchanged it is now possible to define it in terms of a pure crystalline chemical substance. Similarly, while the first standard for Vitamin C was the juice of a lemon this quickly gave place to pure ascorbic acid, and the pure chemical substance calciferol became the international standard for vitamin D in place of irradiated ergosterol.

The international standards for œstrone, androsterone and progesterone were replaced by new samples of the same materials. Since these are pure chemical substances their replacement presents less difficulty because the assurance that the new material is in close agreement, and even identical, with the original standard is forthcoming from a determination of the chemical and physical constants of the two standard preparations. During the war, and in consequence of it, the stocks of the standards for the three important gas gangrene antitoxins, *Cl. perfringens*, *Cl. septicum* and *Cl. œdematiens* had to be replenished to meet the largely increased demand for them in many countries. It is well known that antitoxins may exhibit abnormal properties and, accordingly, particular attention was given to the selection of the samples which were to replace the original international standards. Although the comparative tests on the old and new standard preparations were somewhat limited on account of wartime conditions there is every reason to believe that the replacement standards are representative and have proved satisfactory.

it is within the powers of medical expert advisers in such countries to require that the potency of drugs used within its boundaries shall conform to the requirements of the British Pharmacopœia; and in this way the international biological standards are being brought into use in other lands.

In view of its varied activities and responsibilities, the Medical Research Council has been able to make an effective contribution to this important matter of bringing the international biological standards into effective operation on the widest possible basis. First, on behalf of the Health Organization of the League of Nations it has accepted the responsibility for the final preparation, dispensing, care, storage and supply on a world basis of all the standards except those for antitoxins, antisera and tuberculin: secondly, it has undertaken a similar responsibility, in respect of this group of the international standards, to the Ministry of Health as regards the Therapeutic Substances Act, and thirdly, a like responsibility to the British Pharmacopœia. But the Council's obligations go further than that, because it is also required to supply standards for the antitoxins, antisera and tuberculin, in whatever country these are made and supplied under licence in accordance with the requirements of the Therapeutic Substances Act. Because of these obligations the Department of Biological Standards at Hampstead has had to prepare and maintain standards for antitoxins, antisera and tuberculin; and these are either part of the actual international materials, or they are national standards which have been exactly assayed. The maintenance of these national standards for antitoxins, antisera and tuberculin has not proved difficult, because six of them had been prepared originally at Hampstead and, when handing them over to the international organization, a sufficient quantity of each had been retained to serve the needs of the British Commonwealth and Empire; and very large quantities of equivalent national standards, which have been checked repeatedly at regular intervals with the corresponding international standards maintained at Copenhagen, are also available at Hampstead. The advantage of this additional source of supply of the international antitoxin and antiserum standards was demonstrated in April 1940, when the supplies held at Copenhagen became no longer available to many laboratories which had hitherto drawn their supplies therefrom. In response to a request from the Health Organization of the League of Nations the Medical Research Council was able to supply these standards from the stocks at Hampstead to any applicant requiring them and was glad to make this contribution towards the maintenance of an essential international service.

In a similar way the international standards have become recognized and brought into use in the United States, through the operation of the National Institute of Health and the United States Pharmacopœia, and it is hoped that they will become established in more and more countries through the action taken by national pharmacopœias. Through other activities of the Health Organization at Geneva good progress has been made towards the unification of pharmacopœias and in this way, too, the international biological standards and units may be expected to receive extended recognition and application.

The table shows that the rate of progress of this work has been steady, continuous, and indeed rapid and it did not stop entirely during the war since the standards for vitamin E, for heparin and for penicillin were adopted in this period. At the end of 1938 practically every country in the world was receiving some or other of the international biological standards. The basis for a world-wide organization had then been created and its development was arrested only by the outbreak of war.

The Replacement of International Biological Standards

Since these 35 standards were established it has been necessary to replace more than 20 of them. In some cases this was because the world demand was so unexpectedly large that the first estimates and supplies were on an entirely inadequate scale: in other cases, as for example the standards for androsterone and progesterone, the world stocks of the standard material available at the time of their adoption were so small that the first supplies were absorbed almost at once. In some cases replenishment became necessary because the existing standard no longer conformed to the manufacturers' products of higher purity which advances in knowledge had made possible. Whatever the cause, the work of providing these replacement standards is among the most onerous and exacting which is undertaken at Hampstead on behalf of the Commission because upon its efficient performance and its precision depends the integrity of the international units. With every such replacement it is first necessary to ensure that the material selected for the new standard is representative and satisfies every condition originally or subsequently laid down by the Permanent Standards Commission for that

become the antigen of choice in many countries. During the war this subject has been investigated in some detail at Hampstead and the results suggest that biological standardization of diphtheria prophylactics is practicable, although the form may be different from that which has been attempted elsewhere and hitherto, and international agreement may be forthcoming.

During this war the efficacy of tetanus toxoid for the active immunization of man has been proved beyond doubt, and a uniform system of assessing the potency of these preparations is desirable and here, again, international action might very well become an early priority for the consideration of the new international organization. Investigations carried out at Hampstead during the war suggest that comparative methods of assay, in relation to a standard, using guinea-pigs as test animals may be practicable; in Canada and India mice are favoured as test animals, and an early question for study would be to determine whether the results obtained are independent of the species of animals used. This investigation might also throw some light on the perennial problem of the complexity of tetanus toxin and antitoxin.

Some of the investigations which we have had to carry out at Hampstead regarding the standards for, and the assay of, the gas gangrene antitoxins which became urgent and important because of the immediate needs of the war also indicate new directions in which this work may develop. After the war had been in progress for some time doubts were expressed as to the adequacy of the international standard for gas gangrene antitoxin (perfringens)—commonly known during the war as Welch antitoxin. Briefly, the criticism was that while the standard provided the means for the assay of α -antitoxin, other activities of the organisms, such as its power to produce hæmolysins and hyaluronidase and the bearing of these on infection, and of the antibodies to them in the control of the disease, had not been taken account of and provided for. This was a serious criticism because, if these other antigens were of significance and importance and if the antibodies to them could be shown to be important in the control of the disease then clearly these antibodies should be provided in Welch antiserum in adequate amounts which could be measured by reference to a more complete international standard, or a series of standards which, it was suggested, should be provided. The whole subject was investigated by Dr. D. G. Evans in the only way available at Hampstead, i.e. by the experimental method in laboratory animals. The results of Evans' work are interesting and important: by carefully controlled quantitative experiments he has shown that α -toxin is the most important product of the Welch bacillus which he has investigated up to now, as far as the infection of guinea-pigs is concerned, that its production in culture is closely related to the virulence of the organism, and that the antibody to this toxin is extraordinarily effective in prophylaxis and, provided the conditions for its administration are favourable, it is reasonably effective as a therapeutic agent in animals in which the infection has not proceeded too far. He has not been able to assign a similar importance to other antigens in the infection due to *Cl. welchii*, nor to their antibodies in the prevention or treatment of the infection in guinea-pigs. These results are interesting for two reasons: first, work in this field does not end with the preparation of a standard, but it is often—as in this instance—the starting point for new investigations. The results of these experiments, on a strictly comparable and quantitative basis made possible by the very existence of the standard and unit, have provided new information and new suggestions and ideas concerning the action of antitoxin in controlling a rapidly progressive fatal infection in susceptible animals; and secondly Evans' work has indicated an approach, by *in vivo* methods, to the study of multiple antigens and their corresponding antibodies which, among other things, may enable those concerned to decide which of these antibodies are of importance and, accordingly, for which of them standards should be established.

International biological standards may find useful application in the rapidly developing field of chemotherapy. Pure substances can usually be fully described in chemical and physical terms, the doses to be administered can be expressed as a weight, and biological standards and units are neither necessary nor desirable. It is otherwise, however, in the case of substances of proved biological activity and clinical usefulness of which the chemical composition is unknown and of which, it may be, successive batches exhibit varying biological properties. For such substances, and in the interim period pending the discovery of their chemical composition and structure or of a more reliable process of manufacture, experience has shown the value of the adoption of a standard by comparison with which other preparations can be matched. And similarly, it is not unreasonable to suppose that penicillin is but the beginning and forerunner of similar substances with antibiotic properties and, as the chemical nature of these may

Purified protein derivative (P.P.D.), which is virtually the active principle of tuberculin in solid form, is now so easily prepared and characterized, and is obviously so much more suitable for use as a standard than the crude "old tuberculin" which has hitherto served for this purpose that its adoption as the international standard is a foregone conclusion. Moreover, the replacement of the liquid "old tuberculin" by a stable solid preparation provides the opportunity for defining a unit of tuberculin activity, and this might be useful in human and veterinary medicine in interpreting and comparing the results of tuberculin tests in different animal species.

FUTURE DEVELOPMENTS

In this inter-war period, then, through the activities of the Permanent Commission on Biological Standardization, biological standards have been established for thirty-five important substances, and those who have been intimately concerned with this work hope to see a new international organization created to maintain and extend it.

It is quite likely that one of the first things such a body would do would be to examine and revise the list of standards enumerated in the table. Science and medicine have moved fast and far in recent years and, for various reasons which we can appreciate and with which we might agree, the new Commission might decide that standards for the antisera and some of the antitoxins could be dispensed with and that arsphenamine, the original "606", has surely earned an honourable retirement. The position of the vitamin standards might also come under review because, thanks to the establishment of biological standards and units and the sound principles of assay which these gave, progress towards their isolation in the pure condition, the determination of their chemical nature and in some cases their synthesis have been so rapid that now, not only have the original crude materials used as standards been replaced by pure chemical substances, but chemical and physical methods for their assay—so much more precise, quicker, economical and satisfactory than biological methods—are available for some of them, and likely to be forthcoming for the others. For methods of biological assay are adopted, not as a matter of choice, but more often through dire necessity as the only means of determining the activity of important remedies; and when in addition dosage is no longer on a basis of units but on the more customary basis of weight the question may well be raised as to whether these vitamin standards and units are any longer necessary. As Dale has picturesquely put it "the ultimate aim of all progressive work on biological standardization, as of all preventive medicine, may be regarded as self-extinction". Partly for the same and partly for other reasons the new international body might bring under review the position of the standards and units for some of the sex hormones. Accordingly the number of international biological standards and units maintained at the present time might be very materially reduced.

Developments during the war years indicate some of the directions in which biological standardization may be expected to advance when peacetime conditions and activities are fully restored.

The standardization of the diphtheria prophylactics is a problem of outstanding importance and urgency. Work in this field had been begun under the auspices of the Commission many years before the war but little progress had been made. This may be ascribed, in the main, to the difficulties inherent to the assay of antigens, and this is due to the extreme variability in the animal reaction to antigenic stimulus; in such circumstances very large numbers of animals are required if the comparative tests for potency are to be of quantitative value and significance. Thus, in Germany where a formol-toxoid standard has been established, 250 guinea-pigs are required for the carrying out of the assay in the way required by Frankfurt. Moreover, the fact that different types of prophylactic were used in different countries complicated the situation and made international agreement difficult. In France, Canada and most of the countries on the European Continent the use of formol-toxoid prevailed. In the United States of America, although practice was passing over to the use of alum-precipitated toxoid, at least two other antigens were being used, while in this country alum-precipitated toxoid and toxoid-antitoxin floccules were the antigens of choice, formol-toxoid and toxoid-antitoxin mixture being favoured in certain areas, but on the whole passing out of use. Accordingly, even if simple, practical, economical and reasonably accurate methods of comparative testing had been available, more than one standard would have been required. In these circumstances it is hardly to be wondered at that in many countries—Britain, Canada and the United States for example—the official requirements called for little more than proof of identity and of some evidence of antigenic activity. The post-war situation, however, offers some prospect of progress in this field; the varieties of antigen have been reduced somewhat, the use of alum-precipitated toxoid has increased and bids fair to

Hypertension

By T. IZOD BENNETT, M.D., F.R.C.P.

WHEN we realize that over a hundred thousand persons die in England and Wales every year from the effects of hypertension, it is evident that this condition has become one of the real captains of the men of Death. "The Captains and the Kings depart". and it is because I believe that we are on the verge of obtaining mastery over this scourge that I have chosen it as the subject of this Address. It has been discussed in this Section as lately as 1941 (*Proc. R. Soc. Med.*, 35, 309), and still more recently by the Section of Urology in 1943 (*Proc. R. Soc. Med.*, 36, 551), but the advance of medical science is so rapid and persistent that there is every reason for frequent review of so important a subject.

The full control of any disease or morbid state is almost invariably achieved in three distinct stages, the first in which the condition is recognized and defined, the second in which the clinical and laboratory phenomena associated with it are discovered and recorded, and the final stage in which the reasons for the occurrence of the condition are at last clearly understood. These three stages are answers to the questions What? How? and Why? When for example Addison first wrote on pernicious anæmia he answered the question "What?" and there followed a period of many years during which a mass of knowledge was acquired concerning the appearances of the patients, the various complications, the hæmatological findings, the results of gastric analysis and so on, giving us very full answers to the question "How?" But it was only when Castle at last demonstrated the effects of loss of the intrinsic factor that we had our answer to the final question "Why?" And thereupon the control of pernicious anæmia was achieved.

In the case of hypertension the initial stage, the recognition and definition of the condition, was very slow of accomplishment. Seventy years ago the followers of Bright were searching, ardently but unsuccessfully, for the explanation of certain phenomena which did not fit fully the conception of the master. Spasm and sclerosis of terminal arteries were described and commented on, and the doubts of the medical scientists were well expressed in a famous lecture in which Sir William Gull said of certain specimens showing a hypertrophied heart and a sclerotic kidney that despite his veneration for anything connected with Bright he felt that not the heart and kidneys alone but the whole man should have been preserved in the vase! Twenty years later Allbutt had not yet completely clarified the situation, for we find him in 1895 choosing the term "senile plethora" to describe patients with essential hypertension rather than

remain unknown for varying periods; the establishment of standards and the definition of units may prove as useful as in the case of penicillin.

History will assign to the period between the two world wars a high place for discovery and advance in scientific knowledge. When this claim is made the minds of men turn naturally, if nowadays a little uneasily, to their triumphs in the physical sciences; yet the advances made in the biological sciences have brought, in their practical applications to the needs of man's daily life, a measure of improved health, physical well-being and consequent happiness which will bear comparison with any of his more material gains.

Some of the outstanding advances in this period have been referred to in this lecture, and there are others: the period has seen the discovery of insulin, a greatly increased knowledge of the vitamins and of their chemical nature, the discovery of the drugs of the sulphonamide type and of penicillin, of mepacrine and D.D.T., and of materials for the prevention of diphtheria and tetanus; and we have seen these discoveries bring to the diabetic an almost normal life, almost a revolution in the science of nutrition, the abolition of tetanus as the scourge of armies, protection for the individual or the community against diphtheria, and new triumphs in the prevention and treatment of infectious disease.

In some of these general advances biological standards have played a modest but useful part; and it is not unreasonable or an exaggeration to claim that this work has proved to be essential to research, and the consequent extension of our knowledge in many of those biological sciences on which the progress of medicine depends.

President—T. IZOD BENNETT, M.D., F.R.C.P.

[October 23, 1945]

Hypertension

By T. IZOD BENNETT, M.D., F.R.C.P.

WHEN we realize that over a hundred thousand persons die in England and Wales every year from the effects of hypertension, it is evident that this condition has become one of the real captains of the men of Death. "The Captains and the Kings depart", and it is because I believe that we are on the verge of obtaining mastery over this scourge that I have chosen it as the subject of this Address. It has been discussed in this Section as lately as 1941 (*Proc. R. Soc. Med.*, 35, 309), and still more recently by the Section of Urology in 1943 (*Proc. R. Soc. Med.*, 36, 551), but the advance of medical science is so rapid and persistent that there is every reason for frequent review of so important a subject.

The full control of any disease or morbid state is almost invariably achieved in three distinct stages, the first in which the condition is recognized and defined, the second in which the clinical and laboratory phenomena associated with it are discovered and recorded, and the final stage in which the reasons for the occurrence of the condition are at last clearly understood. These three stages are answers to the questions What? How? and Why? When for example Addison first wrote on pernicious anæmia he answered the question "What?" and there followed a period of many years during which a mass of knowledge was acquired concerning the appearances of the patients, the various complications, the hæmatological findings, the results of gastric analysis and so on, giving us very full answers to the question "How?" But it was only when Castle at last demonstrated the effects of loss of the intrinsic factor that we had our answer to the final question "Why?" And thereupon the control of pernicious anæmia was achieved.

In the case of hypertension the initial stage, the recognition and definition of the condition, was very slow of accomplishment. Seventy years ago the followers of Bright were searching, ardently but unsuccessfully, for the explanation of certain phenomena which did not fit fully the conception of the master. Spasm and sclerosis of terminal arteries were described and commented on, and the doubts of the medical scientists were well expressed in a famous lecture in which Sir William Gull said of certain specimens showing a hypertrophied heart and a sclerotic kidney that despite his veneration for anything connected with Bright he felt that not the heart and kidneys alone but the whole man should have been preserved in the vase! Twenty years later Allbutt had not yet completely clarified the situation, for we find him in 1895 choosing the term "senile plethora" to describe patients with essential hypertension rather than

"hyperpiesia" which was the name he finally employed. On the whole I feel that it is not to Allbutt nor to Huchard that the chief credit for the early recognition of hypertension should be given, but to Mahomed who, in a brilliant series of articles in the *Guy's Hospital Reports* before and after 1880, not only recorded clinical observations but confirmed these by the application of an instrument of scientific precision, Marey's sphygmograph.

By the closing years of the last century the question "What?" was answered, the recognition of the morbid process, hypertension, was accomplished. And then comes a further long interval, amounting to some forty years, during which physicians and pathologists supplied the manifold answers to the question "How?"

It is essentially in the present century that our profession has come to recognize the predominant part played by hypertension in the production of cerebral disasters and cardiac failure; the conception of malignant hypertension has emerged; the part played by hypertension in the production of retinitis, renal sclerosis, and—in spite of somewhat tardy recognition by obstetricians—in many of the greater disasters complicating pregnancy has become apparent.

A mass of knowledge has accumulated, but in spite of this much of the work has been negative in character and the researches of chemists and microscopists—so fruitful in other directions—have accumulated facts rather than the explanation. The third question, "Why?" remains unanswered, and because of this the control of hypertension has barely begun.

Nevertheless we have, in quite recent years, entered on a new epoch, and the final answers will soon be available.

If we examine the diseases most closely associated with hypertension we find that they fall into three groups, (a) nephritis, (b) certain endocrine disorders, and (c) eclampsia. Taking these in reverse order, it is clear that obstetricians have not yet got beyond the fringe of the problem, and the records of Siever and others of the promising results of caudal anaesthesia contrast with the obscurity which still lies behind the screen formed by the term "toxæmia of pregnancy". Time may show that the real linkage here is with the endocrine disturbances such as we see in Cushing's syndrome and certain adrenal tumours, in which hypertension is an outstanding feature. Nephritis remains the overwhelming association with hypertension, and just as it was nephritis which led to the first recognition of hypertension, so it is experiments connected with the kidney which have at last thrown light on essential causal factors.

EXPERIMENTAL WORK

The problem of why hypertension develops has undergone an extraordinary change since the exciting work of Goldblatt and his school. These observers showed how, by artificially diminishing the renal circulation, hypertension, of serious degree could be produced in animals without alteration of the better-known chemical constituents of the blood. Important though this work is, its greatest impetus has come from the work of Byrom and Wilson who, in a series of experiments as brilliant in conception as in technical execution, demonstrated that partial occlusion of the renal artery on one side in the rat would lead to severe hypertension, would produce changes similar to those seen in malignant hypertension in the non-clamped kidney, and, further, that subsequent removal of the clamped kidney could be followed by complete recovery of the other. How this is brought about has not yet been finally established, but it has demonstrated the extreme importance of the "vicious circle", hypertension resulting from interference with the kidney, renal damage increasing the hypertension, which must be a frequent, possibly constant, factor in the mechanism of production of this disorder.

Simultaneously with this work there have been going on other inquiries of a more chemical nature consisting of the isolation of pressor substances from the blood and tissues of normal and hypertensive subjects—both man and animal.

The first important work of this kind is perhaps that of the Swedish physiologist Tigerstedt, but it is really only much later that the experiments of I. H. Page and others have led to recognition of the real importance of these chemical phenomena. Much work has been done both here and in the Americas by Pickering, Page, Grollman and others on "Renin", "Hypertensin", "Anti:renin" and other protein substances derived from the blood plasma, sometimes from normal and sometimes from the victims of nephritis or malignant hypertension. Therapeutic results have already been claimed in experimental animals, but application to man is still awaited.

THE THIOCYANATES

One of the few practical contributions to the therapeutics of hypertension is the potassium thiocyanate treatment. No one has as yet put forward any proof as to how this substance acts. Cavinass has recently stated that it is by replacement therapy, that the blood thiocyanate is below normal in all sufferers from hypertension, but he has produced no proof of this assertion. It is perhaps this lack of scientific explanation, together with the risk of toxic effects from overdosage and the necessity for somewhat frequent blood analysis, that has made us slow in employing this treatment on a large scale. But although its action is uncertain and its use requires great care, there is no doubt at all that potassium thiocyanate does sometimes give dramatic results in properly selected cases.

Barker and his co-workers claim improvement in 50% of 246 cases observed for two to ten years. Cavinass, Kurtz and others in the U.S.A. claim a reduction of systolic blood-pressure of 15% in more than half the cases treated. It is admitted, indeed urged, that the drug is useless if the hypertension has been long established, it is further admitted that if the right blood level is not established by laboratory control serious toxic results may follow, including the onset of acute goitre as described by Potter, Foulger and others. But I cannot permit the criticism of the over-cautious or the scepticism of the ultra-scientific to divert me from the fact that this treatment is to-day the only treatment we possess to combat a disease which kills some hundred thousand people every year in England and Wales.

It is doubtful if thiocyanate therapy will survive, but it will probably disappear not on account of its uncertainties or dangers but because it will be replaced by something more effective. I believe that the new treatment, which we shall see emerge soon, will result from the researches of a group of scientists who desire the preservation of humanity rather than its destruction, who choose to devote their lives to the study of the body rather than to the perfection of the bomb.

Dr. Clifford Wilson (*Experimental hypertension and Bright's disease*) said that, during the last ten years experimental hypertension had made a notable contribution to the understanding of Bright's disease. High blood-pressure had been produced in many animals by a variety of operations on the kidney, the common underlying factor apparently being renal ischaemia. The most significant features of experimental renal hypertension were as follows:

- (1) The increase in peripheral vascular tone which gives rise to the high blood-pressure is brought about by a chemical and not a nervous mechanism.
- (2) The ischaemic kidney may show no microscopic evidence of structural damage.
- (3) Constriction of one renal artery will give rise to persistent hypertension, particularly in the rat, so that failure of renal excretion is not the primary cause.
- (4) Increasing the load on the kidney increases the blood-pressure response.
- (5) Hypertension due to unilateral renal ischaemia gives rise to vascular and parenchymal changes in the opposite kidney and in other organs.
- (6) These closely resemble the lesions of malignant hypertension and chronic interstitial nephritis in man.
- (7) Hypertension may persist after removal of the ischaemic kidney.

Dr. Wilson discussed the work carried out by Dr. Frank Byrom and himself (1939, 1941) which was unfortunately interrupted by the war but which had been largely confirmed by other workers.

He demonstrated by lantern slides the technique of renal artery constriction in the rat and showed typical blood-pressure tracings following this procedure. Photomicrographs were shown illustrating the varieties of acute and chronic hypertensive lesions which were found in the opposite kidney, and the absence of histological changes in the ischemic kidney. That the latter was protected from the hypertension by the clip on the renal artery was indicated by the absence of medial hypertrophy in the arteries distal to the clamp. The arteries of the opposite kidney on the other hand showed great medial hypertrophy.

Application of the results of these experiments to the problems of Bright's disease had helped to clarify certain aspects which had hitherto remained obscure both to clinicians and histologists.

(1) The most significant conclusion was that hypertension can produce in the kidney arterial, glomerular and parenchymal changes which have previously been considered as inflammatory in origin. Since the time of Ziegler and Jores pathologists had made a sharp distinction between arteriosclerotic or ischemic, and inflammatory lesions of the kidney. This histological subdivision should be modified so as to include under the former heading not only the well-recognized chronic ischemic changes but also the acute hypertensive lesions which he had just described.

(2) The malignant form of essential hypertension is established as a distinct clinical and histological entity in which renal damage is secondary to the hypertension. In the early stages it had been shown that structural changes in the kidney were minimal. Malignant nephrosclerosis was the end-result of this disorder.

(3) To the common observation that renal disease gives rise to high blood-pressure we had added the concept that high blood-pressure can produce rapidly progressive renal destruction. Taken in conjunction these premises suggested the possibility of a vicious circle in which renal ischemia leads to hypertension, and this in turn, by causing renal vascular lesions, aggravates the renal ischemia. Wilson and Byrom obtained considerable evidence that such a vicious circle developed in the experimental animal. Its operation in the human subject would explain the rapidly progressive clinical course of malignant hypertension and of other forms of hypertensive Bright's disease in their terminal stages.

(4) The recognition that the inflammatory lesions in the kidney which had been termed "chronic interstitial nephritis" could be hypertensive in origin explained why this picture was common to so many varieties of chronic Bright's disease. Chronic interstitial nephritis was not a disease but a histological compost which represented the end-result of hypertensive renal damage. In malignant hypertension this was the complete picture; in primary renal disease some residue of the original process such as nephritis or pyelonephritis might also be recognized.

(5) The recent accounts of hypertension due to unilateral renal disease in man provided a striking counterpart to the animal experiments. Removal of the diseased kidney might result in relief of the hypertension. On the other hand the possibility of secondary hypertensive damage in the opposite kidney should be borne in mind for such changes had been found post mortem. This might explain the failure of nephrectomy to lower the blood-pressure in some cases. Indeed there was a risk of aggravating the hypertension by removing a functioning though diseased kidney and thereby increasing the load on the opposite kidney whose reserve was seriously impaired. It was suggested that nephrectomy should only be undertaken for the relief of hypertension when intravenous pyelography revealed a single non-functioning kidney with a normally excreting opposite kidney. If, however, the hypertension was clinically malignant, i.e. papilloedema was present, nephrectomy should be undertaken as a life-saving measure even though renal function was slightly impaired. Remarkable success had followed such operations but it was emphasized that cases of this type were extremely rare.

Dr. Mary Lockett: When essential hypertension became clearly established as a clinical syndrome, and the absence of renal insufficiency other than in a very late stage of the disease was widely confirmed, interest in the kidney as a possible causal agent rapidly declined. For some time interest was focused on the adrenals. Frequent coincidence of adrenal cortical hyperplasia and essential hypertension was noted, but it was not a constant finding. Plasma from hypertensives was found to have a greater

constricting effect on strips of surviving artery than plasma from normals, but sensitive biological tests proved this to have been incorrectly attributed to adrenalaemia. This theory was perforce abandoned.

Goldblatt's work did not become widely known until 1934; immediately a great amount of work began on kidney press juices, extracts, and autolysates. Tigerstedt and Bergmann in 1898 had shown the presence of a heat labile non-dialysable pressor compound peculiar to extracts of renal cortex. The purification of renin, and the way in which it carries out its pressor action, were arrived at mainly by two groups of workers, one in North and the other in South America; they used different terminology. [I shall use the South American terminology, adding the North American in parentheses.]

Renin has been shown to be an enzyme, liberated from the renal cortex into the blood-stream where it acts on a blood globulin, hypertensinogen (angiotonin activator), to form the one pressor compound of the renin system, hypertensin (angiotonin).

Renin.—The enzymatic action of renin is proteolytic, but it acts only on hypertensinogen (angiotonin activator) and not on other proteins. This is known because pepsin can replace renin in the conversion of hypertensinogen (angiotonin activator) to a pressor compound. Renin is an antigen, but the development of a high precipitin titre does not reduce its physiological action. Renin also shows species specificity: human renin will act on the hypertensinogen of all mammals, but that of other mammals will not act on human hypertensinogen (angiotonin activator). This species specificity has been used in the development of the biochemical methods for the assay of renin.

The site, either of renin storage or of its formation, has been localized to the proximal convoluted tubules. It is only excreted in the urine after very large doses.

Hypertensinogen (angiotonin activator).—Hypertensinogen is a blood globulin on which renin acts proteolytically to form the pressor compound hypertensin. This globulin has been characterized, and electrophoretically identified with the α_2 globulin fraction. It is made in the liver. The exhaustion of the hypertensinogen in the blood was at one time postulated as the explanation of renin tachyphylaxis, but this has been disproved. Although pepsin will react with hypertensinogen to form a pressor compound pepsitensin, physiologically similar to hypertensin (angiotonin), hypertensin and pepsitensin are not identical; only the former is destroyed by the enzyme hypertensinase (angiotonin inhibitor).

Hypertensin (angiotonin).—Hypertensin is the pressor compound formed by the action of renin on the hypertensinogen. It is thermostable, dialysable, and fluorescent. It is precipitated by saturation with ammonium sulphate, by phosphotungstic acid, but not by trichloroacetic acid. It is soluble in various organic solvents but not in ether. It is more resistant to acids than to alkalis. It was thought to be a polypeptide carrying phenolic OH groups necessary for its pressor action since it was inactivated by tyrosine and aminopeptidase. In accordance with this theory inactivation of the tyrosine by five minutes' boiling destroyed its ability to attack hypertensin; but forty minutes' heating at 60°C. was found to have destroyed the normal enzyme action of tyrosine, yet it still inactivated hypertensin. It is doubtful therefore what conclusions should be drawn from the foregoing observations. Hypertensin was isolated from the venous blood of ischaemic kidneys; but it has been shown that the kidney excretes not hypertensin, but renin.

Hypertensinase (angiotonin inhibitor).—An enzyme that destroys the activity of hypertensin was detected in the blood, and was named hypertensinase.

This completes the review of the components of the renin system.

The pressor action of renin and hypertensin.—The rise in blood-pressure following the intravenous injection of hypertensin is immediate and short-lived. Repeated doses produce equal responses. Renin, on intravenous injection, produces a slow rise of blood-pressure, maintained at plateau level for some time, and falling slowly to the resting level. Repeated doses of renin produce progressively less response; this refractoriness is usually referred to as renin tachyphylaxis. Purification of renin has not eliminated the tachyphylaxis. The shorter the time interval between injections of renin, the more rapidly does the tachyphylaxis develop. The injection of hypertensinogen does not prevent the development of tachyphylaxis; destruction of the nervous system or perfusion of large amounts of fresh blood does not alter renin tachyphylaxis. These results led Page to the theory of renin inhibitor; depressor extracts were obtained from kidney and muscle which on oral administration or on injection were claimed to lower the blood-pressure of animals only in the presence of renal hypertension.

Renin has been shown to be present in the blood in many cases of experimental renal

The Training of Clinical Teachers

PRESIDENT'S ADDRESS

By Professor NORMAN B. CAPON, M.D.

Those who have taken a special interest in the subject of medical education will be aware that there have been occasional references, in recent years, to the question of the teachers themselves—and especially to their fitness and competence to carry out their educational duties.

By way of explanation I should say that I am speaking of *all* clinical teachers—whether they specialize in medicine, surgery, paediatrics, dermatology, ophthalmology, &c., because I am concerned with education in general and teaching methods in general, rather than with the content of the subject taught. And here let me interpose the observation that paediatricians have adhered more closely to the tenets and discipline of the art and science of medicine than any of the specialists; and this is to be expected because paediatrics is in fact general medicine during a particular age-period. Indeed, I would go further, and claim with some assurance that the contribution made to general medicine by paediatricians has been considerable; and I believe that the conditions, both personal and professional, of our work place us in an unusually favourable position for promoting improvements in basic medical education. To do this would be a service well worthy of the great traditions which we have inherited from men like West, Cheadle, Barlow and Still.

Clinical teachers have in the past been inclined to blame the preclinical teachers when students come to the wards without any adequate acquaintance with the general principles of science. There is probably some foundation in this complaint, but it does not exonerate clinical teachers from a share of responsibility if they themselves perpetuate the error which they impute to their preclinical colleagues. Perhaps if we put our "clinical" house into better order we may encourage others to do likewise.

After this brief introduction I shall refer to some of the statements which have been made regarding clinical teachers. The Goodenough Report, concerned with "the

hypertension and essential hypertension, but its responsibility for the hypertension of renal ischaemia cannot be said to have been clearly established by the usual methods of assay, and further work is needed to establish whether it is in fact the causative, or the only causal agent. The results of slow renin infusion experiments give cause for some doubt as to whether a sustained increase of renin secretion could produce prolonged hypertension; for instance, Hill and Pickering found that by slow infusion of renin into normal anaesthetized rabbits it was difficult to maintain a rise of arterial pressure of more than 30 mm.Hg for four hours, faster injections gave a larger temporary rise followed by a fall. After infusions have been continued for some time, tachyphylaxis develops.

Huidibro and Braun-Menendez were able to demonstrate that considerable lowering of the blood-pressure in normal unanaesthetized dogs as a result of trauma or haemorrhage was immediately followed by the liberation of renin from the kidneys into the blood-stream. Although anoxaemia did not prevent the secretion of renin under these conditions, such a sudden liberation of renin into the blood-stream could not be produced by anoxaemia alone.

The properties of renin would make it appear possible that renin is normally concerned with the regulation rather than the maintenance of normal blood-pressure, and the development of tachyphylaxis gives cause for doubt whether excess of renin can be responsible for a persistently elevated blood-pressure.

There is little doubt that following the production of a reduced blood supply to a kidney a chemical agent is secreted which produces a pathological state indistinguishable from essential hypertension. The initial cause for the liberation of this chemical agent in the disease itself and the nature of the chemical agent have not yet been clearly demonstrated.

The Training of Clinical Teachers

PRESIDENT'S ADDRESS

By Professor NORMAN B. CAPON, M.D.

THOSE who have taken a special interest in the subject of medical education will be aware that there have been occasional references, in recent years, to the question of the teachers themselves—and especially to their fitness and competence to carry out their educational duties.

By way of explanation I should say that I am speaking of *all* clinical teachers—whether they specialize in medicine, surgery, pædiatrics, dermatology, ophthalmology, &c., because I am concerned with education in general and teaching methods in general, rather than with the content of the subject taught. And here let me interpose the observation that pædiatricians have adhered more closely to the tenets and discipline of the art and science of medicine than any of the specialists; and this is to be expected because pædiatrics is in fact general medicine during a particular age-period. Indeed, I would go further, and claim with some assurance that the contribution made to general medicine by pædiatricians has been considerable; and I believe that the conditions, both personal and professional, of our work place us in an unusually favourable position for promoting improvements in basic medical education. To do this would be a service well worthy of the great traditions which we have inherited from men like West, Cheadle, Barlow and Still.

Clinical teachers have in the past been inclined to blame the preclinical teachers when students come to the wards without any adequate acquaintance with the general principles of science. There is probably some foundation in this complaint, but it does not exonerate clinical teachers from a share of responsibility if they themselves perpetuate the error which they impute to their preclinical colleagues. Perhaps if we put our "clinical" house into better order we may encourage others to do likewise.

After this brief introduction I shall refer to some of the statements which have been made regarding clinical teachers. The Goodenough Report, concerned with "the

organization of Medical Schools, particularly in regard to facilities for clinical teaching and research," contained the following observation (p. 41, para. 15): "In the past too little attention has been paid to the training of teachers of medical students"; and in the same paragraph of the Report one reads: "Help and guidance in the acquisition of skill in the difficult and subtle art of teaching will enable an intending teacher to avoid much fruitless expenditure of time and effort in preparing himself for his important duties and will greatly assist him to make the most effective use of his personal qualities."

The Report of the Planning Committee of the Royal College of Physicians of London (1944) stated on p. 8: "We wish to draw attention to the importance of quality in teaching" but it does not indicate how that quality is to be secured and maintained, except by a reference to the value of the tutorial method in teaching.

Sir Thomas Lewis [1] in his "Reflections upon Reform in Medical Education" referred to the differences between vocational and theoretical training, and pleaded that students should be encouraged to develop a more thoughtful and critical outlook; in his view the whole-time teachers of the future should provide the cultural (as distinct from technical) training of the students, as a supplement to that given by clinical teachers, who would be mainly responsible for "vocational" tuition.

The B.M.A. Committee [2] which was invited to prepare a memorandum of evidence for the Goodenough Committee stated: "Students should be taught the fundamental principles of health and disease rather than the diagnosis and treatment of separate diseases. A thorough knowledge of fundamental principles will produce a more understanding practitioner who will be able readily to absorb the advances in medical knowledge and technique as they occur during his career. Many practitioners at the present time find difficulty in keeping abreast of modern medical progress because they did not acquire a sufficient foundation in their student days." This memorandum evidently assumes that we teachers are competent to provide the type of basic education which it advocates.

I think it is possible that there is general agreement regarding the wisdom contained in these various observations—at all events in so far as broad principles are concerned. But we must consider their practical implications. How, in fact, are we to ensure that while the student learns what is essential of factual knowledge, he shall at the same time be given a real education—a basis upon which he can continue to build from his own experience because he understands general principles? It is not enough for us to recommend a modification of the subjects which comprise his curriculum, or a change of the type of clinical material demonstrated to him (substituting patients with common disorders for those suffering with rare diseases), nor to be satisfied with a pious hope that the lecturer, busily engaged in a place devoted to the injured and sick, shall remember to remind the students that some people, at any rate, are healthy, though they may require advice if they are to preserve that health. These and other such recommendations may be wise and, if put into practice, may constitute valuable reforms; but they are the individual facets of one stone, the limbs and separate parts of one body, and it is to the heart of that body that we must turn our minds. For it is from the teacher that the life-blood of education flows. In this regard I cannot do better than quote from the article on Education which is to be found in the *Encyclopædia Britannica*:

"All education is effected through the experiences of the educated, but it does not follow that all experiences are educative; this depends upon whether its form has been arranged by those who are concerned with the training of him whose experience it is."

And again:

"The goodness or badness of an education will be relative to the virtue, wisdom and intelligence of the educator. It is good only when it aims at the right kind of product, and when the means it adopts are well adapted to secure the intended result and are applied intelligently, consistently and persistently."

We clinical teachers may reasonably claim to be experienced and competent practitioners of medicine; can we claim also that we are trained educators? I submit that, with a few exceptions—the born teachers, or the men of unusual vision, or those who, in spite of the busy calls of professional life, have made a special study of their teaching duties—we cannot make this claim. How, then, are we to ensure that our successors in clinical teaching shall be more competent? or, at least, shall have the opportunities to develop greater competence in this direction? Clearly this is a matter for the Universities themselves—and not, I would submit, for all Universities to undertake initially; an experiment might be started in one or two centres where there may happen to be a group of enthusiastic teachers. The plan, as I see it at present, might be as follows: In a given University a small group of senior teachers, aided by one or two preclinical teachers and

the Professor of Education, would hold preliminary discussions and would arrange a vacation course, perhaps three weeks in duration, for junior clinical teachers—e.g. registrars and assistant physicians, surgeons and specialists. The number of those taking the course should be restricted, perhaps to fifteen; and some at least of them should come from other centres in order that the discussions, which would form an important feature of the course, should represent the views and habits of different schools. The following aspects of medical education would require treatment, partly as lectures, partly as discussions and in some cases by demonstration:

- (1) The meaning of education, with some reference to educational methods in general.
- (2) The scope and aims of medical education with special reference to (a) undergraduates; (b) graduates, including general practitioners, specialists and consultants, research workers, public health workers and administrators.
- (3) The historical approach in medical education: and the value of non-medical literature.
- (4) The artistic (or humanistic) approach.
- (5) The scientific method, with special reference to experimental inquiry. Its clinical application, including the technique of medical examination.
- (6) Elementary logic, including critical analysis of evidence and assessment of values. Statistics.
- (7) The technique of clinical teaching.
- (8) The place of psychology in teaching.
- (9) The use of medical libraries.
- (10) The preparation of scientific reports and papers.

[Professor Capon then commented upon some of these topics and indicated, in greater detail, what they comprised. He also offered for consideration the following list of books and papers which would be of interest to those studying the subject.

- | | |

organization of Medical Schools, particularly in regard to facilities for clinical teaching and research," contained the following observation (p. 41, para. 15): "In the past too little attention has been paid to the training of teachers of medical students"; and in the same paragraph of the Report one reads: "Help and guidance in the acquisition of skill in the difficult and subtle art of teaching will enable an intending teacher to avoid much fruitless expenditure of time and effort in preparing himself for his important duties and will greatly assist him to make the most effective use of his personal qualities."

The Report of the Planning Committee of the Royal College of Physicians of London (1944) stated on p. 8: "We wish to draw attention to the importance of quality in teaching" but it does not indicate how that quality is to be secured and maintained, except by a reference to the value of the tutorial method in teaching.

Sir Thomas Lewis [1] in his "Reflections upon Reform in Medical Education" referred to the differences between vocational and theoretical training, and pleaded that students should be encouraged to develop a more thoughtful and critical outlook; in his view the whole-time teachers of the future should provide the cultural (as distinct from technical) training of the students, as a supplement to that given by clinical teachers, who would be mainly responsible for "vocational" tuition.

The B.M.A. Committee [2] which was invited to prepare a memorandum of evidence for the Goodenough Committee stated: "Students should be taught the fundamental principles of health and disease rather than the diagnosis and treatment of separate diseases. A thorough knowledge of fundamental principles will produce a more understanding practitioner who will be able readily to absorb the advances in medical knowledge and technique as they occur during his career. Many practitioners at the present time find difficulty in keeping abreast of modern medical progress because they did not acquire a sufficient foundation in their student days." This memorandum evidently assumes that we teachers are competent to provide the type of basic education which it advocates.

I think it is possible that there is general agreement regarding the wisdom contained in these various observations—at all events in so far as broad principles are concerned. But we must consider their practical implications. How, in fact, are we to ensure that while the student learns what is essential of factual knowledge, he shall at the same time be given a real education—a basis upon which he can continue to build from his own experience because he understands general principles? It is not enough for us to recommend a modification of the subjects which comprise his curriculum, or a change of the type of clinical material demonstrated to him (substituting patients with common disorders for those suffering with rare diseases), nor to be satisfied with a pious hope that the lecturer, busily engaged in a place devoted to the injured and sick, shall remember to remind the students that some people, at any rate, are healthy, though they may require advice if they are to preserve that health. These and other such recommendations may be wise and, if put into practice, may constitute valuable reforms: but they are the individual facets of one stone, the limbs and separate parts of one body, and it is to the heart of that body that we must turn our minds. For it is from the teacher that the life-blood of education flows. In this regard I cannot do better than quote from the article on Education which is to be found in the *Encyclopædia Britannica*:

"All education is effected through the experiences of the educated, but it does not follow that all experiences are educative; this depends upon whether its form has been arranged by those who are concerned with the training of him whose experience it is."

And again:

"The goodness or badness of an education will be relative to the virtue, wisdom and intelligence of the educator. It is good only when it aims at the right kind of product, and when the means it adopts are well adapted to secure the intended result and are applied intelligently, consistently and persistently."

We clinical teachers may reasonably claim to be experienced and competent practitioners of medicine; can we claim also that we are trained educators? I submit that, with a few exceptions—the born teachers, or the men of unusual vision, or those who, in spite of the busy calls of professional life, have made a special study of their teaching duties—we cannot make this claim. How, then, are we to ensure that our successors in clinical teaching shall be more competent? or, at least, shall have the opportunities to develop greater competence in this direction? Clearly this is a matter for the Universities themselves—and not, I would submit, for all Universities to undertake initially; an experiment might be started in one or two centres where there may happen to be a group of enthusiastic teachers. The plan, as I see it at present, might be as follows: In a given University a small group of senior teachers, aided by one or two preclinical teachers and

of the specialism which rightly claims him as a master and wrongly tempts him to become its slave.

Fourthly, can a teacher learn anything worth knowing of medical education in a three weeks' vacation course? I do not claim that such a course can do more than present a view-point, inspire interest and suggest a practical curriculum for study. Here is the first stone of an educational foundation upon which the teacher can build; his proficiency will grow with practice. But he will be stimulated to ask of himself three all-important questions: *Why* am I to teach? *What* am I to teach? and *How* am I to teach? and to seek intelligent answers to these questions. There must be no interference with the liberty and originality of the teacher who, in accepting the role of educationalist, takes upon himself a burden of responsibility no less heavy than that of clinician. But are we being fair to him in denying him the opportunity of organized study?

Sir Adolphe Abrahams: I am dubious of the possibility of systematically educating teachers, I mean, of course, of clinical medicine. The application of pedagogy may well be successful in respect to general education but medicine seems to me to be in an isolated category. So much depends on the teacher's personality. One man may be completely didactic, another may adopt the Socratic method, and a third may say exceedingly little and yet create an atmosphere from which his followers appear to absorb instruction. And all may be equally successful yet fail miserably if called upon to employ a style or method foreign to their individuality.

Moreover one has to remember that the teaching directed to assist students to pass their examinations and that which prepares them for the real business of their professional lives are by no means the same thing. An exceptional man may combine the two functions but it seems unfortunate that the majority of teachers are far too much influenced by the problem of Queen Square and similar ordeals. It is often urged that some place should be found in the curriculum for a course of instruction by a general practitioner. That students could learn much from a practitioner of experience needs no emphasis, so for that matter can consultants. But although a course of lectures might comprehend certain technicalities that are features of practice, I think that little of real value can be communicated by word of mouth. The opportunity of a sort of apprenticeship in order to study the methods would provide a valuable experience but such an arrangement could hardly be practicable.

I deprecate the growing tendency to delegate the teaching of undergraduates to men of the registrar class. These, however brilliant academically, have not the maturity to inculcate the fundamentals. A common error is to confuse education with instruction. Students are only too ready to welcome spoon-feeding but teachers are not required to save them from taking trouble although they may direct them in the way of taking trouble and perhaps save them from taking unnecessary trouble. There is a further great advantage in the status of the senior, the prestige which is naturally associated with a position on the Honorary Staff adds enormously to the value of his *ex cathedra* pronouncements.

A final word about postgraduate teaching. Whilst in my opinion undergraduate teaching in this country is the best in the world, the quality of postgraduate instruction calls for considerable improvement. It is not difficult for anyone who has studied on the Continent to supply reasons for our comparative inferiority but doubtless this aspect of medical education will receive special attention by those who will be responsible for organizing the future.

Sir Ernest Rock Carling said he thought a great deal could be done by a faculty of pedagogy giving instruction in method, towards turning the young clinician into an effective teacher.

The clinical teacher's education should begin with the humanities; not necessarily Greek and Latin classics. A competent knowledge of a foreign language giving access to a great literature was what was wanted. To make for clarity in speaking, as in writing, some instruction in linguistics was desirable. A teacher should understand the true function of words and how they should be adapted to the level of conversation.

At some period after qualification, travel to and work in other clinics at home or abroad was very valuable. Thereafter visits in the company of colleagues gave exceptional opportunities for heart to heart exchange of experience. Without them it was difficult to maintain a standard of self-judgment.

It was not to be expected that all men should do fruitful research, but a period served in a research department was valuable as an initiation into scientific method and way of thought. At least it taught accuracy of observation and something of the value of statistics. The use of the library, books and records, should be learnt by the production of contributions to the literature. The memory should not be taxed by attempts to cover the whole field, but full factual acquaintance with all the data in some specialized part should be at command.

It will be apparent that the subject matter of the course is divisible into two sections: (a) basic education and (b) the technique of teaching. The former is the more important because it concerns itself with general principles, and clinical teachers who are prepared to devote some time to studying this aspect of their duties will be the better able to ensure that their students are in fact educated as well as vocationally equipped. In parenthesis I should state that no part of the tuition given to teachers is intended to be directly transmitted to students, and I stress this because it would be a mistake to believe that I am advocating that students, at all events during their clinical years, should find their curriculum made still more congested by the inclusion of lectures on logic and kindred subjects.

Perhaps I may best expand the theme of this address by considering some of the criticisms or objections which are likely to be put forward. First, it may be argued that junior clinical teachers have little time and sometimes little inclination for work which is not strictly technical or vocational. Lack of time is a defect which is likely to be corrected by a change in policy regarding teaching duties, for which little if any direct payment has been made in the past. Teaching, and preparation for teaching, takes time and it is very probable that this service will be put on a proper financial basis in the near future. We shall, I think, all agree that the best medical education cannot be provided by clinicians who must, by force of circumstances, regard their teaching duties as subsidiary to their routine professional service. At present it is true to say that most clinical teachers have scarcely time even to think; but the wisdom of the medical educator no less than that of the scribe cometh by opportunities of leisure, and I believe that one of the strongest arguments in favour of a vacation course such as I advocate will be found in the inspiration and renewed enthusiasm which it is likely to bring to junior clinicians.

As for lack of inclination I can only state my own experience of young clinical teachers, which is that they are most anxious to learn and to improve their competence as teachers.

Secondly, it may be argued that there are at present no clinical teachers, even among the seniors, who are equipped for the difficult task of conducting a course on the general lines suggested, and that the work would therefore have to be "farmed out" to non-medical educationists, scientists and philosophers whose ignorance of medicine would be a fatal handicap. It is my view that if the suggested course is to be effective in a practical way it must be conducted mainly by practising clinicians, perhaps with the advice and assistance of non-medical specialists; and I would go further and plead that it would be mistaken policy to leave this basic education entirely in the hands of clinicians whose experience is largely, if not solely, confined to hospital practice. If we accept, as I think we must, that practising clinicians capable of taking charge of such a course are at present few in number, the fact must be regarded as a strong argument in favour of correcting such a deficiency in the future. A start must be made; it will be pioneer work, with all the thrill and excitement of a new venture, and I am confident that its ultimate success will give new point to the conception that the intellectual function cannot afford to stand still, but must be growing and developing if it is to retain full health and vigour.

Thirdly, the view has been put forward, in discussion, that teachers are born, and cannot be made; and that if a clinician is really proficient in his professional work and "knows his stuff", the student learns both by precept and example. Indeed, the fear has been expressed that a clinician's skill in practice and his ability in handling patients may be jeopardized by overmuch attention to theory and rationalization. There is some substance in this argument, for we must all know clinicians of the "research" type whose critical scientific attitude has resulted in a certain diffidence of manner and flabbiness of authority in the sphere of human relationships which has been detrimental to their success in therapeutics. I give place to no one in my respect for the really first-class practising clinician—whether he be general practitioner or specialist; to me he represents the highest degree of excellence that has been attained in our profession. But we do him less than justice if we assume that by an active effort to broaden the basis of his knowledge and cultivate wisdom he will thereby reduce his technical efficiency. And it is not sufficient that the teacher should "know his vocational stuff", though that is, of course, a *sine qua non*; he must possess intellectual poise and expansiveness of mind if he is to guide students wisely through the narrow and complicated pathways

of the specialism which rightly claims him as a master and wrongly tempts him to become its slave.

Fourthly, can a teacher learn anything worth knowing of medical education in a three weeks' vacation course? I do not claim that such a course can do more than present a view-point, inspire interest and suggest a practical curriculum for study. Here is the first stone of an educational foundation upon which the teacher can build; his proficiency will grow with practice. But he will be stimulated to ask of himself three all-important questions: *Why* am I to teach? *What* am I to teach? and *How* am I to teach? and to seek intelligent answers to these questions. There must be no interference with the liberty and originality of the teacher who, in accepting the role of educationalist, takes upon himself a burden of responsibility no less heavy than that of clinician. But are we being fair to him in denying him the opportunity of organized study?

It was not to be expected that all men should do fruitful research, but a period served in a research department was valuable as an initiation into scientific method and way of thought. At least it taught accuracy of observation and something of the value of statistics. The use of the library, books and records, should be learnt by the production of contributions to the literature. The memory should not be taxed by attempts to cover the whole field, but full factual acquaintance with all the data in some specialized part should be at command.

For the rest, "apprenticeship" was the real substance of the education needed. His own plan with a chief assistant was to take him for a year, during which he laid himself out to teach the prospective surgeon all he knew. If satisfied, he took him for a second year, during which he acted as assistant to the young man. At the end of that year, if convinced there were the makings of a surgeon, he kept him on for a third year, with full responsibility, acting himself merely as consultant. With the close of that year he felt he could recommend him to any clinic that would accept him to complete his education.

Dr. Ffrangcon Roberts: Having long felt that medical education should be approached from the point of view of education I heartily welcome the President's scheme for the training of teachers and hope he will be enabled to put it into effect. The faults in medical education, the overcrowding of the curriculum, the excess of factual information and the absence of training in logical thought have been stated so often in recent years that their repetition makes wearisome reading. The problem is no longer what is wrong, but why, when everyone knows what is wrong, no remedy can be found. I believe that the President has pointed one way to the solution.

My experience as Manager of three Council Schools has taught me that the problem is by no means confined to medicine. Leading educationists are fully aware of the perpetual struggle which the observational and naturalistic approach perpetually wages against the tyranny of the textbooks and stereotyped class instruction. Nevertheless it is to them a matter of constant study and experiment, and one cannot help contrasting their enthusiasm with the stagnation and inertia which beset medical education. There are many outside our profession to whom we might listen with profit.

As long ago as 1918 Sir George Newman pointed out that medical education had not kept pace with the advance in medicine. The reason of course is that medicine is studied but medical education is not studied. We shall make no progress until we realize that the presentation of the curious combination of science and art of which medicine is composed is a subject which requires intensive training and study. One way to keep interest alive in this matter would be the formation of an Education Section of this Society.

Section of Anæsthetics

President—GEORGE EDWARDS, M.R.C.S., D.A.

[November 2, 1945]

Tribromethyl Alcohol (Avertin, Bromethol), 1928-1945

PRESIDENT'S ADDRESS

By GEORGE EDWARDS, M.R.C.S., D.A.

TRIBROMETHYL ALCOHOL is more commonly known as avertin. It is also known as bromethol in this country and as bromethanol in the United States. I propose to use these terms interchangeably as may be convenient.

Starting with a few tentative cases in 1928, the use of avertin became popular and widespread and only with the later introduction of more convenient drugs and methods has that popularity waned. From my own figures I find that in 1936 20% of hospital patients and 65% nursing home cases were given avertin. During the last twelve months I find that less than 5% of hospital cases and under 10% of private cases have had this drug, and my colleagues assure me that their experience is similar to my own.

In 1927 notices began to appear in the medical papers describing the use in Germany of a new anæsthetic agent named by its makers "Avertin" and numbered "E107". This new drug, it appeared, was the answer to all anæsthetic problems. The patient went peacefully to sleep in bed half an hour beforehand, was completely and safely anæsthetized, and woke up some two or three hours later, with no sickness, no headache and very little pain. The only bar to its use was said to be disease of the rectum, colon, kidney or liver. A quantity of this new drug was obtained for trial here, and was distributed by the Anæsthetics Committee, which had been set up jointly by the Medical Research Council and the Council of this Section of your Society. Some of the avertin to be tried was sent to Dr. Shipway at Guy's Hospital and some to Dr. Blomfield at St. George's. As resident anæsthetist to the latter, it fell to my lot to discover all that there was to be known about the preparation of the drug for use, and to make arrangements for trying it out.

It appeared that avertin was tribromethyl-alcohol, a white crystalline solid, soluble in water to something over 3% at 40° C. If such a solution was given rectally in quantity equivalent to 0.1 gramme per kilo of body-weight, then absorption of the drug would gradually produce anæsthesia, reaching its greatest depth in thirty to forty minutes and lasting up to two hours. The other salient point was that the solution must be freshly prepared and that it must be tested by the addition of Congo-red solution prior to use. If a blue colour appeared, or, indeed, anything but bright orange-red, then the solution must be discarded as dangerous. It seemed that a decomposition into dibromacetaldehyde and hydrobromic acid might take place—the former was dangerous and the latter was indicated by the change of colour in the Congo-red. The advantages held out for this form of anæsthesia were not only the preliminary narcosis and the peaceful awakening, but also the absence of sickness and of post-operative chest troubles. Rectal anæsthesia was by no means new: ether-oil was well known and paraldehyde had been largely used but neither had become popular.

All that now remained was to use the avertin. One of the surgeons expressed his willingness to co-operate, or, rather, he agreed not to object. We asked to be told when there was a simple operation to be performed on a healthy subject. It came in the form of an exploration of the floor of the mouth in a young woman suffering from salivary calculus. The operation took place on March 20, 1928, and, as far as I can discover, this was the first occasion on which tribromethyl alcohol was used in this country. I wish to recount the case in some detail, solely to point out the differences between what we then did and anticipated, and what we now consider to be reasonable.

We started off with a rectal washout accompanied by the hypodermic injection of one-third of a grain of omnopon. 4.8 grammes of avertin crystals, representing 0.1 per kilo of body-weight, were dissolved in 160 c.c. of distilled water, making a 3% solution. That sounds a simple enough business but in fact it meant a great deal of shaking and was wearisome and tedious. The solution, finally achieved, was found to be acid-free on addition of the Congo-red and was run into the patient's bowel, taking seven minutes. With the idea of assisting in its retention, the catheter was removed and a vaseline-wool

plug was placed in position. The patient rapidly dozed off, and in fourteen minutes it was observed that the conjunctival reflex was absent and the corneal reflex was faint. In three more minutes the corneal reflex had also gone and there was no response to pinching the skin of the thigh. The surgeon was invited to proceed and his incision into the floor of the mouth was made twenty-three minutes from the time we had begun the injection of the avertin. No objections were raised by the patient until the surgeon delved deeply into the sublingual tissues. This brought a groan. Shortly afterwards, there was a cough. The actual operation lasted seventeen minutes and the patient was returned to the ward with her corneal reflex still absent. A thorough rectal washout was started at once. Recovery and convalescence were uneventful.

On the whole, we were very pleased. The avertin had produced almost complete anaesthesia, nothing untoward had occurred and the patient had certainly had a much easier time than was the usual lot in those days when premedication consisted of atropine only, and when the porters who brought a case from the ward stayed in the anaesthetic room to hold it down during induction. We were unable to get any subjective views on the matter; not only had the patient never been anaesthetized before, but we had taken every precaution to prevent her from knowing that anything unusual was happening.

No doubt various items in the account of this case have caused you to raise your mental eyebrows. I would ask you to remember that all this happened a long time ago—seventeen years and a half—in what has been unkindly referred to as the "age of dark anaesthesia when 'closed ether' was still popular". My own comments on this case are nine in number, and I will try to deal with them as briefly as possible.

(1) There was a pre-premedication with omnopon. This helped in the anaesthesia; but, as was later remarked by Sir Francis Shipway, the same result could be attained with less respiratory depression either by a small amount of additional inhalation anaesthetic, or even by a relatively slight increase in the avertin dosage.

(2) The drug was supplied in crystals and had to be weighed out and dissolved. In the following year (1929) "avertin fluid", as we know it to-day, was available, and preparation of the dilute solution became a comparatively simple matter.

(3) A 3% solution was used. The usual strength is now 2½%: the volume is not unduly increased, the mixing is easier, and there is less danger of the avertin crystallizing out.

(4) A rectal washout was given just before the administration. This was an unnecessarily vigorous proceeding. In any case, it was ill-timed; if the bowel is emptied by washout or by enema, it should be allowed to rest for an hour or two before being expected to retain a further injection.

(5) A cotton-wool plug was used lest the fluid be returned. In spite of the use of such plugs—or more probably because of their irritation—we used occasionally to lose our avertin in the bed sheets. It was soon evident that greater safety was achieved either by gently withdrawing the catheter or, even better, by leaving it in situ carefully clipped.

(6) The depth of anaesthesia was tested by examining the conjunctival and corneal reflexes. Apart from the fact that poking one's finger into a patient's eye is strongly to be deprecated in any circumstances, it was very obvious that the narcosis produced by avertin was against the ordinary run of things. The patient might have lost his ocular reflexes, but he could still kick back when attacked by the surgeon or, as in this particular instance, could cough when blood trickled into the larynx.

(7) Full surgical anaesthesia was expected with this standard dose. We did not anticipate any need for supplementary inhalation.

(8) Such completeness was in point of fact not attained. The patient was sensible enough to retain her laryngeal reflex and to protect herself against the passage of any foreign material into her trachea.

(9) A rectal washout was given at the end of the operation—over an hour from the time of starting the avertin injection. This was useless: it would neither prevent further absorption, nor assist in elimination.

Such, then, was the first case. The next was a gastrectomy, and went very happily. Herniotomies and appendicectomies followed satisfactorily. An attempt was made to get complete anaesthesia for the removal of a large thyroid cyst. The omnopon was increased to two-thirds of a grain, and the avertin was at the rate of 0.125 gramme per kilo. The resulting anaesthesia was complete and satisfactory, but, unfortunately, permanent, the patient dying some twenty hours later without recovering consciousness. By this time, it was evident that only very small doses of inhalation anaesthetic were required to complete a partial avertin anaesthesia, and it was decided henceforth to use only the standard dose of avertin—or, in other words, to seek for basal narcosis rather than complete anaesthesia.

On March 16, 1929, the *Lancet* (i), 546, published a paper by Drs. Blomfield and Shipway. It bore the title, "The Use of Avertin for Anæsthesia" and summed up the results not only of their own cases, but also the observations made by Mr. Basil Hughes of Bradford, Mr. F. J. Morrin of Dublin and Dr. F. P. de Caux. The paper was published at the request of the Anæsthetics Committee which had distributed the samples. In its penultimate paragraph was a verdict, which ran: "We consider avertin to be a valuable addition to the drugs at the disposal of the anæsthetist and that if it is used with due care and moderation its advantages can be taken advantage of with perfect safety."

This cautious approval seems to be slightly complicated in its wording but it provided the "Go-ahead" signal, and avertin was put on general sale to the profession. The manufacturers, however, were cautious too. They labelled it, "The Basal Narcotic", indicating that its true use was preliminary to rather than productive of anæsthesia.

From 1930 onwards there appeared in the medical papers almost innumerable articles, annotations and letters on the subject of avertin narcosis. It was used in conjunction with local anæsthetics, with spinals, and with every kind of general anæsthetic, even including chloroform. All users were unanimous in its praise, and reading back over the literature, one begins to feel that a competitive game was being played as to who could use bromethanol in the youngest, the oldest, the most obese or the most dangerously ill patient. It is not needful to refer to the majority of these articles, but certain of them were of particular importance.

Very much to the point was the paper by W. P. Kennedy on "Effective Counteraction of Avertin Narcosis". This was a timely document for, although it was abundantly clear that avertin narcosis in routine dosage was safe for normal patients, restorative measures then known were not very effective in dealing with the respiratory and circulatory depression which occurred when a comparative overdose chanced to be given. Washing out the rectum was of little use unless the untoward symptoms were observed before all the avertin had been absorbed—and this would only occur when a gross overdose had been given. The only thing to do was to keep the patient going and wait for gradual recovery. Carbon-dioxide-oxygen and ephedrine were found to help, and varying views were expressed as to the value of thyroxin. The way in which thyrotoxic patients effectively disposed of normal and larger doses of avertin immediately suggested that an artificial thyrotoxicosis, by the giving of the hormone, should be an effective restorative measure. Pribram published in Germany in 1929 a paper stating that intravenous thyroxin was effective. The particular cases he describes are not very convincing proofs of its value, and other observers failed to find it of use. Indeed, one writer found that the thyroxin had to be given for some days before becoming effective! This was not much help.

Kennedy, however, followed up and confirmed an assertion made in Germany by Killian that avertin narcosis could be quickly and effectively counteracted by the intramuscular or, better, intravenous injection of pyridine beta-carboxylic acid diethylamide. This drug is now our old friend coramine, and our rechristened colleague nikethamide. Kennedy used this stimulant on avertinized cases in Dr. James Young's gynæcological clinic in Edinburgh, and was able to report very favourably on its value, saying that "Coramine is an effective agent in counteracting and interrupting the cardio-respiratory depression of avertin anæsthesia, which occasionally reaches a point where active measures are necessary to overcome it".

Though there was no doubt that with careful choice of case and with reasonable administration, avertin overdosage was an unlikely event, we now had the moral support of knowing that an effective stimulant was at hand.

From the very beginning it had been suspected that tribromethyl alcohol, being a halogen compound, would be a potential danger to the liver. Unfortunately, pharmacological investigations did not produce very clear-cut results; it was difficult to decide how much importance was to be attached to the various tests of liver function. Wesley Bourne of Montreal experimented on dogs and showed that "repeated administration in normal dogs produced only a mild parenchymatous degeneration of the liver and kidneys: fatty changes in the liver occurred occasionally; when they did, they were very slight". In 1933, however, in collaboration with L. H. McKim, Bourne reported on a patient who had had twenty-two avertinizations within a period of ten weeks. The unfortunate man had had a severe infection of the leg following a road accident, and had needed a series of painful dressings. Bourne investigated the liver function by bromsulphalein dye retention tests, by observing the pigment metabolism, and by determining sugar tolerance. His report was that "even after the twenty-two doses there was no retention of the dye, which compares very favourably with the action of one dose of this or any other anæsthetic agent". Such changes in pigment excretion and of the blood-sugar concentration as were observed were not cumulative, were referable to the patient's general condition, and were not observable at the time of the twenty-second administration.

Meanwhile, anæsthetists in general were seeing but little evidence of hepatic damage due to or aggravated by avertin. In the first paper, Blomfield and Shipway record an instance of the drug having been used successfully in a jaundiced patient operated on for gall-stones. In 1932 H. K. Ashworth reported three successful cases of avertinization in the presence of definite hepatic damage. By 1935 Sir F. Shipway was able to record 1,600 cases of avertin administration, in only two of which had there been any evidence of liver disturbance. Both these cases had had avertin plus ether, and both had shown a slight but transient jaundice post-operatively; one was a child with a long history of acidosis, and the other an adult who at operation was seen to have a cirrhotic liver. These two cases could hardly be regarded as an indictment of avertin, and from the same series Sir Francis was able to quote two cases of very ill and jaundiced patients who made uninterrupted recoveries even though they were given this narcotic.

On both sides, then, the pharmacological and the clinical, it seemed that avertin was harmless to the liver and, further, that even the damaged liver was no contra-indication to its use. Nevertheless Rabinovitch of Montreal, in discussing Bourne's findings, says, "Avertin should be used with great care in the presence of an obviously damaged liver (jaundice, &c.)", whilst Shipway concludes that avertin may be administered in a dose "suitably adjusted" to patients suffering from jaundice, cirrhosis or other forms of liver damage.

Now in real point of fact, these apparent permissions amount to practical prohibition. To use avertin "with care" or in "suitably adjusted doses" requires more detailed knowledge of pharmacology in general, and of the individual patient's pathology in particular, than falls to the lot of the common or garden administrator of anæsthetics. What is of value is the realization: (a) That avertin used in the normal way is unlikely to damage a healthy liver, and (b) that if there is any suspicion of interference with hepatic function, avertin should be avoided, notwithstanding the many recorded cases in which it has been safely used in the presence of liver damage.

Kidney function and the use of tribromethyl alcohol are, of course, intimately related. Again, there are two aspects of the problem: the excretion of the detoxicated drug, and the effect of the drug on normal renal activity. F. B. Parsons of Cambridge investigated the excretion of the drug in rabbits, and was able to publish a paper on his findings as early as October 1929. This was followed by similar investigations by other workers, and very little was agreed upon other than that half or more of the combined brom-ethanol was excreted during the first day after injection, and that the remainder took several days. Much more positive were the findings of E. N. Pitt of Guy's Hospital, who investigated the effect of avertin on human renal function. This work was undertaken at the request of the Joint Anæsthetics Committee which we have already mentioned and the findings were published in the *Lancet* of March 30, 1935. In his conclusions, Pitt states that: "In spite of the conditions which tend to hamper renal function during anæsthesia, nitrogen excretion is actually very little upset by the volatile anæsthetics and less so by avertin."

Meanwhile, the value of avertin narcosis in cases of thyrotoxicosis had been more and more appreciated. From the beginning it was seen that hyperthyroid patients tolerated the drug extremely well, and that they were particularly benefited by effective pre- and post-operative narcosis. It soon became evident that the surgical treatment of Graves' disease had changed from being a dangerous and harassing adventure to a reasonably safe calm routine affair. It is in this field that avertin has been of greatest service. Many papers and notes were published in the Journals on this, and I refer to two of them only. Among the first of these was an early account in the *British Journal of Anæsthesia* for October 1930 of Ivor Lewis's observations on 20 cases either of Graves' disease or of toxic adenoma, in which anæsthesia was preceded by avertin narcosis. The series was small, but the cases were carefully observed and the results were an encouragement to further trial, and a sample of what was to come. The second paper covers a series of 243 operations on 220 patients, and was published by Mr. Geoffrey Keynes in the *British Medical Journal*, 1934 (i), 844. In recording an immediate operative mortality of only 1%, the author remarks that the general operative risk of most of his cases was considerable, and that he "cannot avoid the conclusion that this low mortality is to be attributed to some extent to the systematic use of rectal avertin".

On September 9, 1933, H. K. Ashworth of Manchester startled us by an article in the *British Medical Journal* showing that our confidence in Congo-red was misplaced. He showed that solutions which were apparently neutral on testing with Congo-red appeared as acid when tested by "Universal Indicator". In actual fact, many of us jibbed at this new idea and might, perhaps, be described as "Congo-red reactionaries". It has since been stated that Universal Indicator is too sensitive and that it will condemn many a

good solution. Be this as it may, I must say that Ashworth should be considered as being in the right; better that a sea of innocent solution be wrongly poured down the drain than that one dose of decomposed avertin be given.

Since tribromethyl alcohol had proved a satisfactory narcotic, why should not trichlorethyl alcohol be equally as good? Molitor and Robinson in 1938 published in America an account of the effects observed when this drug was given orally to mice and rats, and rectally to dogs and rabbits. They found it to be slightly more hypnotic than bromethol, but to cause less respiratory depression. It was not seen to cause any damage to any of the animal tissues, and there would seem to be no objection to its being used in humans. In this country it was tried by Langton Hewer of St. Bartholomew's Hospital and Douglas Belfrage of St. George's. This was again at the instance of the Anæsthetics Committee, and the findings were published in the *British Medical Journal* of December 3, 1938. As this new drug was a stable liquid, and was easily soluble in water, it was disappointing to find that in some cases it caused excitement both during the onset of narcosis and during recovery. This was exactly what bromethol avoided. In all cases there was with the chlorine compound a tendency to tachycardia, more marked in those who were excited. Finally, Case 18 died suddenly from cardiac failure early in the onset of narcosis. The patient, it was true, was an auricular fibrillant, but the suspicion that the trichlorethanol might have produced the untoward result was enough to put an end to further experimentation. D. A. Wood, in the United States, also recorded a death, this of an apparently robust man of 24 who was being encephalographed under chloroethanol. Cardiac failure was preceded by extrasystoles. This case was the American twenty-fifth—and the last. *Sic transit chlorethol!*

It naturally occurred to a number of workers to try avertinization by the intravenous route. Haffner and Kirschner are reported to have injected small quantities for induction in Germany in 1929-30. In 1941 I saw the method used for anæsthesia in Professor Macintosh's Clinic at the Radcliffe Infirmary, and I am told that it was used abroad in the Army, but I have no details of this last.

Two main aspects of the value of avertin still remain for our general survey—its use in cases with chest troubles, and its use for operations in the mouth and throat.

Being absorbed through the colonic mucosa, and being excreted by the kidneys, avertin was at once welcomed as likely to be particularly useful in cases of respiratory disease. The realization that considerable operations could be easily carried out under avertin narcosis, with superadded gas-oxygen only, seemed to give the answer to many of the problems facing us. The introduction of cyclopropane, however, altered the picture quite fundamentally, and the comparative advance of avertinization was a mere faltering before the rapid strides which followed.

It began to be obvious that prolonged basal narcosis was in itself a contributory factor to post-operative chest troubles. This general idea was developed in some detail by Massey Dawkins who, in 1936, published an extensive series of figures from which he demonstrated that the introduction of basal narcosis had been followed by a doubling of the incidence of pulmonary complications. Avertin, then, was not the best answer to surgery in the presence of chest lesions; in fact, it could even be shown to be the wrong answer.

In throat surgery things took an exactly opposite course. Avertin, it was found, affected the cough reflex to an unusually small extent. By 1933 Shipway was able to recount 244 successful tonsillectomies using avertin as a basal narcotic, and it is now the general experience that, with standard dosage and with due discretion in the administration of the supplemental anæsthetic, there is no contra-indication to the use of the drug in these cases.

Indications for the use of avertin as they now appear to me are easily enumerated:—

- (a) Hyperthyroidism, thyrotoxicosis.
- (b) The expressed wish of the patient.
- (c) The absence of easily seen superficial veins, which renders intravenous pre-medication difficult or even impossible.

Contra-indications are more numerous and cover a much wider range. They comprise:

- (a) Inflammations or lesions of the rectum or lower bowel.
- (b) Operations in the region of the rectum, where a dry field is cleaner than one awash with unabsorbed water of our injection.
- (c) Any condition of the patient which produces a definite deviation from the physiological norm—fever, wasting, anæmia, obesity, cardiac or respiratory lesions, hypopæsis, hyperpæsis, gross renal or hepatic lesions and, though it is rarely met with, myxœdema.
- (d) Mental deficiency (of the chin, not the mind). Holding up an absent chin is a task beyond the powers of the ordinary ward staff.
- (e) Shortage of trained ward staff.
- (f) Inability from lack of time or other reason to clear the patient's lower bowel. If in such a case it is still considered advisable to use a rectal anæsthetic, evipan can be substituted; the necessary solution is very small in quantity, and is much less likely to be returned.

This refusal of avertin to all cases which are in any way ill or physiologically abnormal, implies a personal reconnaissance on the part of the anaesthetist. It is to be hoped that this is now a matter of normal routine.

Having decided on avertin, all that we need ask in the way of special preparation is a simple enema given somewhere between twelve and six hours before the operation. Should the patient ask for a sleeping draught the night before, it is as well to reassure and dissuade him. If he insists, the minimal amount must be given and it must be taken at least twelve hours before the intended time of the avertin. One of the few cases I have had where resuscitative measures have been required for depression solely due to the avertin was in a woman who was allowed to take her usual two allonal tablets the night before. What we did not know till later was that her practitioner had also given her permission to take a further two at 2 a.m., if she then found herself awake. This she had quietly done, and although she did not seem unduly sleepy when the nurse went to give the avertin, yet half an hour later she had to be revived.

The dosage of avertin and the giving of adjuvant drugs present entirely different problems according to whether the patient is normal or is thyrotoxic. With normal patients we can use a standard dosage of one-tenth of a gramme of avertin to each kilogram of body-weight, subject to a maximum of 8 grammes. This maximum corresponds to a body-weight of $12\frac{1}{2}$ stones; although we have avoided the purely obese patients, yet it appears in practice that heavy doses are to be avoided even in heavy patients. By happy chance this limit of 8 grammes coincides exactly with the 8 drachms maximum for rectal paraldehyde. Even more incidentally, the rate of one-tenth of a gramme per kilo is very nearly equal to two-thirds of a gramme per stone. This gives a quick rough check on the amount ordered, though it would be barbarous to mix one's categories by ordering in such a manner. With the standard dosage I also order a hypodermic injection of one-hundredth of a grain of atropine to be given ten minutes after giving the avertin, which takes place between forty and thirty-five minutes before the scheduled time of operation.

Although we hear so often that ether is a drug of the dead past, yet it continues to be used in quite large quantities, and I feel that the giving of a small amount of controllable ether to a normal patient is better than reinforcing the avertin with morphia, than increasing the dose of avertin, or than cutting down the oxygen percentage in the gaseous mixture.

Using this standard dose in a standard patient I expect to find and do find pin-point pupils which dilate on my pinching the skin of the forearm. At the same time there is usually a delayed and vague gesture of the arm, and possibly a turning of the head. Were I to try for them, I have no doubt that I should find the conjunctival reflex absent and the corneal reflex very slight.

In dealing with the thyrotoxic patient, the routine we have just considered is of little value; each case has to be treated on its own merits or demerits, and even during the course of the operation, plans may have to be reconsidered. Furthermore, the surgeon's habits as regards local infiltration, and his views on the advisability or otherwise of intubation, have to be taken into account. It would seem that avertin would provide an excellent means of "stealing the thyroid", but I have had a disappointingly large number of failures, largely, I believe, because my cases have been treated in general hospital wards where it seems almost inevitable that some injudicious remark by nurse, charwoman or neighbouring patient gives the game away.

I like my thyroid case to have a hypodermic injection of either morphia one-sixth grain with atropine one-hundredth grain, or of omnopon one-third grain with scopolamine one-hundred and fiftieth grain, preferably the latter, one hour before the operation. Half an hour later I give, or am present at, a rectal injection of avertin at our standard rate. I keep more avertin in reserve and give anything up to a further quarter dose before the actual operation, occasionally before the patient is moved to the theatre. Then, if the operation is difficult or long, I am ready to give a further quarter dose after the lapse of another half an hour.

To summarize this: first the omnopon-scopolamine; in half an hour, a standard dose of avertin; in another half an hour, an additional dose up to one-quarter of the original, if need be; then the operation, with anything up to a further quarter dose at the end of another half an hour, if necessary. This is not a rigid routine, merely the maximum I consider permissible.

Finally, I should like to express my own personal gratitude to one of the authors of that first paper, Dr. Joseph Blomfield, and to record the appreciation due to Messrs. Bayer, the original manufacturers, for the way in which they held up the sale of the drug until the Anaesthetics Committee had reported upon it.

The Eradication of Tuberculosis in Cattle. Disease in Relation To Animal Husbandry

By W. A. POOL, M.R.C.V.S.

DURING the last century there have been enormous developments in the characters of livestock. With improved capacity to grow and store foodstuffs, together with changes in the nature of the fodder grown, there has been a revolution in animal husbandry. Improved breeds with characters particularly valuable to the community have been evolved. Stocking has become heavier, animals which mature much more quickly than their ancestors have developed and their production has reached standards which are out of all proportion to what might be regarded as natural for living creatures. Animals have become machines with a standard of efficiency that even engineers might envy. In selecting animals for breeding the aim has been to produce particular characters, for example, special capacity for production, such as milk yield or carcass type; at the same time stamina and disease resistance have been neglected. Consequently, the environment and systems of husbandry have tended to produce a high disease hazard, which the animal has a limited capacity to withstand unless it is given the extensive protection of such measures as are available from veterinary science.

Infective disease of the chronic insidious endemic type, such as tuberculosis, has proved to be much more difficult to control than the acute plagues, even after its nature was understood.

The wastage from disease in this country is a source of great anxiety to all concerned and this has been evinced publicly by many representative bodies with a knowledge of the position—by the farmers themselves, the National Veterinary Medical Association, Government departments and, in a recent memorable debate, the House of Lords.

The extent of tuberculosis in cattle in Great Britain.—There is a lack of adequate data concerning the incidence of tuberculosis in cattle in this country. The Cattle Diseases Committee of the Economic Advisory Council reported in 1934 that about 40% of the total dairy stock in Great Britain might be considered to be infected. The National Veterinary Medical Association in a recent report accepted an incidence of 40% as a reasonable working figure, stating that local incidence varies from 5% to 90% and that 0.5% of cows yield infected milk. A figure of 7% to 10% is commonly accepted as the incidence of tubercle bacilli in churn milk and it is considered that practically all samples from large bulked milk containers are infected.

Infection in cattle due to tubercle bacilli of types other than bovine.—Infection of pigs with the avian type of tubercle bacillus is common and this type can be passed to cattle from either infected poultry or pigs. The lesions in cattle are of a very restricted nature and do not cause clinical evidence of disease.

The human type of tubercle bacillus can cause a very mild infection in cattle, in this case also without resulting in clinical evidence of disease. Such infection of cattle is considered important in Scandinavian countries.

The significance of infection in cattle with acid-fast bacteria other than the bovine type lies in the fact that the animals become sensitized to tuberculin; this results in an added complication in control measures based upon the removal of reactors to that test. There is another probable cause of sensitization, hitherto of a rather mysterious nature; it is a condition in which there are skin lesions associated with abundant acid-fast bacteria. The organisms have not been cultivated and all attempts to set up infection with them have failed.

Tuberculosis in human beings due to infection from cattle.—G. S. Wilson (1942) and Roodhouse Gloyne (1944) have discussed in considerable detail the extent to which human beings acquire infection from cattle. In non-pulmonary tuberculosis the bovine type of bacillus has been found to be the cause in about half the cases of cervical

gland infection and lupus, one-third of the cases of scrofuloderma and one-quarter of the cases of meningeal, bone and joint, and genito-urinary infection.

When the type of bacillus responsible for pulmonary tuberculosis in human beings was ascertained the bovine type was found to be responsible in from 1% to 8% of cases.

Other infective diseases transmitted by milk to human beings.—G. S. Wilson (1942) emphasized that our knowledge of milk-borne diseases is very incomplete, and that the number of recorded cases of disease represents a gross underestimate of the real incidence. He considered that 400 to 500 cases of *Brucella abortus* infection occur annually in England and Wales, the great majority of these being milk-borne. It may be noted that a herd in Staffordshire was found in 1940 to be infected with *Brucella melitensis* and that two other herds had been found to be similarly infected. It is not expected, however, that this organism will gain a foothold in this country.

Scarlet fever and septic sore throat are not infrequently spread by milk, and epidemics are reported from many countries. The causal organism, *Streptococcus pyogenes*, can cause mastitis in the cow and it appears that an infected attendant can pass the organism to the cow's udder.

Alternatively, the milk can be infected directly by a milk handler. As the organism cannot develop in milk under normal trade conditions, direct infection by a milk handler only causes small outbreaks or sporadic cases, but milk from an infected udder can cause serious epidemics.

The organisms of diphtheria, enteric fever, dysentery and cholera can gain access to milk from infected sources. Milk is believed to play an important part in the causation of summer diarrhoea in infants.

Bact. typhi-murium, *Bact. enteritidis* and *Bact. enteritidis* var. *dublin* cause infection in cattle and in such circumstances the milk may be infected and give rise to epidemics in human beings. Staphylococcal mastitis of the cow leads to the development of the powerful and relatively heat-resistant toxin in the milk, with serious effects on those who consume it. The Government "White Paper" (1943) on Measures to Improve the Quality of the Nation's Milk Supply is an important landmark in the campaign to prevent milk-borne disease.

Farming and Political Economy

The prosperity of farming is dependent upon political matters over which the industry has no control. It has been impossible for farmers to foresee what conditions would prevail for any considerable period in the future. There have been periods of unnatural prosperity, with rocketing prices in time of war, and periods of serious depression between the wars. Political considerations have decided both the competition which has to be met in the sales of the farmers' products on account of importation from countries outside the British Isles, and also the conditions under which many of his essential supplies are imported.

In such circumstances, there has been little opportunity for the individual to depart from accepted practice and the conditions have not favoured the introduction of desirable changes to prevent disease.

The Marketing of Cattle

Systems of marketing cattle in the United Kingdom appear to have evolved which, while providing a certain convenience to the vendor and purchaser, do not give sufficient opportunity for the latter to be reasonably certain that he will obtain a healthy animal. This is rather strange because good health is the first character the buyer expects in his purchase. The buyer relies upon his judgment which is based chiefly on cursory observation of certain external characters: this is of course useless for the detection of disease, except in the case of certain of the more obvious conditions.

Self-contained and "Flying" Herds

For disease control the self-contained herd is in the strongest position. At the other extreme, the "flying herd" is obviously a bad risk with regard to disease. The modern development of the milk industry has led to the adoption of the "flying herd" system on a very large scale. Commercial dairy herds have to maintain a steady output of milk and so cows in milk yield have to be maintained. New purchases have to be made at relatively short notice to replace cows which cease to yield milk. The system of marketing does not provide a good supply of really healthy calving cows of suitable types. Purchases tend to be made blindly; disease is introduced, or perpetuated, and this makes further purchases necessary. In this way the industry is producing its own problems instead of solving them.

It is known that "flying herds" have a high rate of tuberculosis and that they are the most difficult herds to deal with when eradicating the disease.

The Design of Farm Accommodation

Farm buildings are often old and difficult to improve and this requires attention.

Savage (1929) in his book, "The Prevention of Human Tuberculosis of Bovine Origin", was very critical of the hygiene of cowsheds. He said: "Many of the existing cowsheds seem to be constructed and used as if their object was to spread infection as easily as possible." Another quotation from his book is worth recording: "The elaborate evidence as to droplet and cross-infection in dormitories might as well have never been acquired for all the influence it has so far exerted upon cowshed construction." Although this was written sixteen years ago it would be difficult to suggest that it does not apply to farms to-day. Observations made in hospitals during the war on the spread of infection by bedclothes and floor dust have considerable bearing on conditions in houses used for animals.

When planning farm buildings insufficient attention has usually been given to isolation arrangements.

The fact that animals feed off the ground, on which they defæcate and micturate, is of course a key problem which has to be studied in the development of successful animal husbandry. The great advantages which accrue to husbandry from these very habits have been fully utilized; they are natural habits and become problems only when domestication requires a concentration of animals. The problem is the old one of "overcrowding".

Water Supply on Farms

The provision of a suitable supply of pure water is commonly a great difficulty both inside buildings and at pasture. Deficiency in the supply of water available on farms causes serious breakdown of essential hygienic standards. Cleansing is impossible and disease factors are given undue opportunities to operate. A Government "White Paper" on water supplies was issued in 1943 and if the plans there described become operative a great advance will have been made, but it is doubtful if farms will get all the service that is required.

Drainage in farm buildings.—Like water supply, the provision of adequate drainage for farm buildings is important and is often insufficient.

The Pasteurization of Milk

Little need be said beyond assuming that at last there is no serious opposition to its adoption for all milk except that produced hygienically from herds free at least from tuberculosis, brucellosis, mastitis and any other contagious disease, provided that the pasteurization is properly achieved.

It is understood that a pasteurization policy involves adequate measures for the provision of milk from animals that are not infected with the preventable diseases, so a pasteurization policy should not be allowed to hinder the abolition of disease from our herds.

THE CONTROL OF TUBERCULOSIS IN CATTLE

The control of tuberculosis by immunization.—The extent to which large-scale immunization can be used as a serviceable measure for the control of tuberculosis is still unknown. BCG vaccine appears to be at least of some value in suitable conditions for preventing serious clinical manifestations of infection. If further tests of this or any other method of immunization yield evidence that a really useful immunity can be conferred on cattle, such a vaccine could be employed in certain circumstances as part of a control campaign.

The chemotherapy of tuberculosis in cattle.—At a time when specific chemotherapy of bacterial infection is under such intensive study and yielding such spectacular results, it might be suggested that there is justification for delay in commencing eradication by other means, in the hope that some important discovery will revolutionize the position with regard to tuberculosis in cattle. Whatever might be the chance of finding a successful curative agent, it is certain that proof of its efficiency could be provided only after extensive trial, first on laboratory animals and later on cattle. Its cost would have to be low and its administration economical, if it were to be of value for the control of such a widespread disease. Whatever the future may hold in this respect, control by the elimination of infection, using the powers now available to science, should be the aim at the present time.

Meat inspection in relation to the control of tuberculosis in cattle.—In the application of any control plan it would be necessary that important sources of information con-

gland infection and lupus, one-third of the cases of scrofuloderma and one-quarter of the cases of meningeal, bone and joint, and genito-urinary infection.

When the type of bacillus responsible for pulmonary tuberculosis in human beings was ascertained the bovine type was found to be responsible in from 1% to 8% of cases.

Other infective diseases transmitted by milk to human beings.—G. S. Wilson (1942) emphasized that our knowledge of milk-borne diseases is very incomplete, and that the number of recorded cases of disease represents a gross underestimate of the real incidence. He considered that 400 to 500 cases of *Brucella abortus* infection occur annually in England and Wales, the great majority of these being milk-borne. It may be noted that a herd in Staffordshire was found in 1940 to be infected with *Brucella melitensis* and that two other herds had been found to be similarly infected. It is not expected, however, that this organism will gain a foothold in this country.

Scarlet fever and septic sore throat are not infrequently spread by milk, and epidemics are reported from many countries. The causal organism, *Streptococcus pyogenes*, can cause mastitis in the cow and it appears that an infected attendant can pass the organism to the cow's udder.

Alternatively, the milk can be infected directly by a milk handler. As the organism cannot develop in milk under normal trade conditions, direct infection by a milk handler only causes small outbreaks or sporadic cases, but milk from an infected udder can cause serious epidemics.

The organisms of diphtheria, enteric fever, dysentery and cholera can gain access to milk from infected sources. Milk is believed to play an important part in the causation of summer diarrhoea in infants.

Bact. typhi-murium, *Bact. enteritidis* and *Bact. enteritidis* var. *dublin* cause infection in cattle and in such circumstances the milk may be infected and give rise to epidemics in human beings. Staphylococcal mastitis of the cow leads to the development of the powerful and relatively heat-resistant toxin in the milk, with serious effects on those who consume it. The Government "White Paper" (1943) on Measures to Improve the Quality of the Nation's Milk Supply is an important landmark in the campaign to prevent milk-borne disease.

Farming and Political Economy

The prosperity of farming is dependent upon political matters over which the industry has no control. It has been impossible for farmers to foresee what conditions would prevail for any considerable period in the future. There have been periods of unnatural prosperity, with rocketing prices in time of war, and periods of serious depression between the wars. Political considerations have decided both the competition which has to be met in the sales of the farmers' products on account of importation from countries outside the British Isles, and also the conditions under which many of his essential supplies are imported.

In such circumstances, there has been little opportunity for the individual to depart from accepted practice and the conditions have not favoured the introduction of desirable changes to prevent disease.

The Marketing of Cattle

Systems of marketing cattle in the United Kingdom appear to have evolved which, while providing a certain convenience to the vendor and purchaser, do not give sufficient opportunity for the latter to be reasonably certain that he will obtain a healthy animal. This is rather strange because good health is the first character the buyer expects in his purchase. The buyer relies upon his judgment which is based chiefly on cursory observation of certain external characters: this is of course useless for the detection of disease, except in the case of certain of the more obvious conditions.

Self-contained and "Flying" Herds

For disease control the self-contained herd is in the strongest position. At the other extreme, the "flying herd" is obviously a bad risk with regard to disease. The modern development of the milk industry has led to the adoption of the "flying herd" system on a very large scale. Commercial dairy herds have to maintain a steady output of milk and so cows in milk yield have to be maintained. New purchases have to be made at relatively short notice to replace cows which cease to yield milk. The system of marketing does not provide a good supply of really healthy calving cows of suitable types. Purchases tend to be made blindly; disease is introduced, or perpetuated, and this makes further purchases necessary. In this way the industry is producing its own problems instead of solving them.

enhanced price for milk from herds that are free from the disease. Unless there was a considerable difference between the value of the sales from such herds and those still infected there would not be sufficient inducement for the farmer to co-operate willingly. Furthermore to grant such a subsidy would be the fair way to spread the cost of an eradication campaign over the community which would benefit from it.

In the earlier stages of an eradication policy an "Areas Plan" must be used. This is probably universally accepted. In the areas first chosen there should be a good proportion of herds free from the disease, or only lightly affected. The types of cattle-farming practised would influence the choice of areas and the localities selected should have natural boundaries. In such areas all cattle would require to come under control. As the disease was eliminated the areas would be enlarged until ultimately adjacent areas would join, thus making an extensive "clean" area. New areas would gradually be declared until they all joined.

At the same time it would be advantageous if voluntary eradication were undertaken, with full help from the Government, including financial assistance, in parts of the country outside the declared areas. This would tend to increase the supply of "clean" animals for herds under eradication, besides enlarging the number of centres from which the best form of propaganda, actual example, would issue. In this way, too, fresh localities would automatically become ripe for declaration as new *areas*.

For the eradication of tuberculosis from cattle it is axiomatic that the animals should be shielded from infection from other species of animals including birds.

Animals in a latent stage of tuberculosis can of course often be used with a good deal of success. Indeed, if the fact that the infection was present were known and suitable precautions were taken, there would not be a great deal of objection to utilizing a good many animals in this category in certain types of herds until they could be disposed of economically and with safety to the community, provided that adequate precautions were taken to render their products harmless to human beings. Thus reactors free from clinical signs of infection could be moved from herds in the declared area to herds elsewhere and be utilized in this manner, so long as the herd in which they were placed was known to have a large proportion of reactors.

The case for eradicating tuberculosis in cattle rests chiefly upon economic considerations. The disease is responsible for great wastage. It considerably shortens the productive life of the animal, diminishes the return obtained for the food consumed, the replacements needed on account of tuberculosis cause additional expense, and labour is wasted. Tuberculous animal food products have to be condemned as unfit for consumption.

Apart from finance, the difficulty in undertaking eradication in this country arises from two main factors, a shortage of healthy cattle to replace infected animals and a shortage of veterinary surgeons to undertake the work.

There is no short cut for the supply of healthy animals to replace those to be eliminated under an eradication scheme, though much could be done to improve the position in the future. When an efficient eradication policy has been in operation for a certain time, a stage will be reached when so many herds are free from infection that a supply of tuberculosis-free cattle will be available. It is possible that a large number of tuberculosis-free animals could be obtained from the other side of the Atlantic.

The shortage of veterinary surgeons is to be regretted and it is to be hoped that plans at present under discussion will provide them before long. There has perhaps been some undue caution in the calculations of the number of veterinary surgeons required in the future. Tuberculosis is only one of the diseases to be eradicated from our livestock. *Brucella* infection will probably have to be similarly dealt with one day. Future research may be expected to provide means for dealing effectively with certain other diseases which are intractable at present, and there again, for a time, additional veterinary staff will be required. It would be quite safe to make provision for a period of expansion of not less than fifty years, and in these circumstances there need be little hesitation about launching adequate educational schemes for to-day.

ENQUIRY INTO MEANS FOR THE CONTROL OF TUBERCULOSIS IN CATTLE

While much has been said about what could be done, there has not been sufficient general investigation of the situation as a whole. Action to overcome one part of a general problem may increase difficulties in other respects.

Tuberculosis is an example of a disease, for which a far greater and more concerted effort is required than has hitherto been envisaged. The problem involves finance, medical and veterinary science, engineering, public services such as power and water,

cerning the extent and incidence of the disease should be studied. The carcasses of cattle slaughtered for any purpose provide a master-key to the study of the question. It would therefore be specially valuable if there were close collaboration between the departments responsible for meat inspection and for knackeries and other means of disposal of diseased animals. Where necessary the disease could then easily be traced back to the farms of origin, and so provide an invaluable check on the efficiency of the control measures.

It may be added that in the eradication campaign so successfully carried out in the United States of America the Federal Department of Agriculture had this source of information at its command.

Disinfection.—In a tuberculosis eradication campaign disinfection is a most important item. To obtain the best results the use of suitably equipped teams is valuable. In the United States special lorries provided with a petrol-driven pump are used. After the routine cleansing and removal of litter the disinfecting team deals systematically with the building, using a suitable disinfectant applied hot and sprayed under pressure.

Instruction of farmers and their employees on matters concerning disease control.—Those responsible for the care of livestock, including the owner, the man in charge of the herd and the cowman, must understand the conditions which lead to infection and those which control it; how the germ of the disease operates in the body of its host and outside it, and the extent to which an apparently healthy animal can itself develop severe disease, or infect another animal.

In herd management there must be continuity in any system that is practised and this involves the need to ensure that there is no alteration of special routine when one attendant replaces another, such as when duties are changed around while members of the staff are off duty or on holiday. This is often, of course, a matter of extreme difficulty and there is, therefore, all the more need for an inflexible system in order to avoid breakdown.

In spite of the amount of semi-scientific literature that is produced there is a dearth of suitable books and booklets for the layman explaining the manner in which disease can spread and how those responsible for the animals should do their work in order to eliminate this risk. Something roughly comparable to the course of instruction in the first-aid books of the Red Cross and St. John Ambulance Societies is needed, except that it would not deal with first-aid. It should be devised specially for persons with an elementary school education and deal with the hygiene of the farm.

To be effective such instruction should be given so that it is really convincing and is understood; it should therefore be arranged in a manner which is suitable for the mentality of those concerned. There is probably a case for teaching some of the matters concerning disease control in rural schools. Suitable leaflets, handbills and slogans used discriminately would be most useful. Lectures should be given on a wide scale. Suitable instructional films would be of particular value, with arrangements for their exhibition at small gatherings, so that they might be seen repeatedly by most of those concerned.

Complete eradication.—In the United States of America spectacular success has been achieved in a nation-wide eradication campaign and within a quarter of a century the incidence of reactors has been reduced to less than 0.5% in every one of the 48 States. In Canada great success has also been achieved.

In Norway the disease hardly exists in cattle and there was little in Finland when war broke out. Other Scandinavian countries have large numbers of herds free from the disease. In most other countries where tuberculosis is a serious problem the results of control measures have been poor or mediocre, but in some there are large numbers of herds free from the disease as a result of such measures, though with few exceptions the herds are scattered.

In many European countries there has been a serious overestimate for many years of the extent to which tuberculosis can be controlled by the detection by clinical methods of cases of the "open" type and the elimination of such animals from the herds. During the decade prior to the recent war there was a striking change in many countries towards reliance primarily on the tuberculin test. As soon as it was made worth while in various countries for the farmer to rid his herd of the disease, under schemes providing financial assistance to replace reactors and an increase in the price paid for milk from clean herds, good results began to be reported.

It is now quite clear that nothing short of the regular application of the tuberculin test and the elimination of reactors, together with regular veterinary inspection to detect clinically affected animals, will achieve success, and that considerable financial assistance must be given for the replacement of animals that are condemned, together with an

Section of the History of Medicine

President—SIR ARTHUR MACNALT, K.C.B., M.D.

[November 7, 1945]

Some Chapters in Cambridge Medical History V. Clifford Allbutt and the Transition from the Nineteenth Century¹

By SIR WALTER LANGDON-BROWN, M.D.

FORMERLY a speech was delivered annually in the chapel of Caius College, Cambridge, on the progress of medicine from the time of Dr. Caius. On May 11, 1870, it fell to the lot of Thomas Clifford Allbutt to deliver this. In scholarly and eloquent terms he showed that theories of disease were undergoing a great change; disease was not something with an independent existence, but is "the living body in a peculiar state", and the function of the physician was "to put the body in such a position that it may most quickly recover its own balance". He believed that chemical inquiry was already finding the way into many of the remoter secrets of function and looked forward to the construction of some sort of canon for the discovery and adaptation of remedies, "an achievement" as he said "which would at once raise Medicine into the front rank of intellectual pursuits". Far though we may still be from realizing that canon, his other contentions, so apart from the thought of 1870, are now part of our common inheritance and justify him in speaking of him as the exemplar of the transition from 19th to 20th century medicine.

It is impossible here to give a detailed account of all he accomplished in nearly ninety years of life, nor is it necessary since it has been done so admirably by Sir Humphry Rolleston in a book to which I am much indebted for many of the facts I shall relate. In the main I shall concentrate on three things, the forward direction of his thought, his work for the Cambridge School as Regius Professor of Physic, and his remarkable personality as I remember it. Some biographical details are, however, essential.

Thomas Clifford Allbutt was born at Dewsbury, Yorkshire, on July 20, 1836, the only son of the Reverend Thomas Allbutt. His mother was a Wooler, a family closely associated in friendship with the Brontës. Allbutt's impression was that Emily Brontë was a most unagreeable woman, with whom no one could get on except Charlotte, whom he thought "as dull as a governess ought to be". Five of his uncles were medical and he had a free run of the surgeries of two of them and he was fascinated by the strange labels, "mummy powder", "horn of unicorn" and "crabs' eyes". He was also a diligent student of the *Lancet* when only 9 or 10 years old. He had a small laboratory at home where he was always making experiments. His delicacy as a child he afterwards attributed to the "sparkling water" of the Vicarage well that gave him a continued fever, treated by avuncular bleedings, antimony, mercury, and blisters which left lifelong scars on his back. Thus from the very beginning he was interested in the past, suffered from the present and looked forward to the future of therapeutics. He went to the famous and ancient St. Peter's School, York, of which the great Alcuin, who stimulated Charlemagne to found the Cathedral schools, had been Master from 772-782.

His father had been at St. Catherine's College, Cambridge, but he entered Caius in 1855, where he obtained a classical scholarship; however, he soon determined to read natural science. Among his contemporaries there were four men all destined to become well known in medicine, Howship Dickinson, W. B. Cheadle, George Hare Phillipson and Peter Wallwark Latham, with the last-named of whom he later came into conflict, while the first-named was a lifelong friend. He graduated alone in the first class of the Natural Sciences Tripos, which had been established only eight years previously, although music, art and literature had attracted him at Cambridge more than science. Nevertheless he attended the teaching of George Paget and George Humphry at Addenbrooke's before going to St. George's Hospital whither Dickinson also went. He was clinical clerk to Bence Jones of whose brilliant and whimsical personality he has left an entertaining account. J. W. Ogle also had a considerable influence on him, directing his attention to the ophthalmoscope. He also worked with Lockhart Clark. Bence Jones advised him to study in Paris where he attended the clinics of Trousseau, Charcot, Duchenne and Bazin, and became very friendly with Raynaud. Thus he received a thorough grounding in mid-nineteenth century medicine.

Returning to England in 1861 he decided that, with his Yorkshire associations, Leeds was the place for him to settle in, and there he remained for twenty-eight years. Almost at once he was elected physician to the Fever Hospital, where he introduced fresh air, as an important factor in the treatment of typhus, and methods of prevention of post-typhoid thrombosis. His experience there enabled him in Cambridge, in 1903, to recognize an outbreak of alastrim for what it was, though doubters dubbed it "All-but smallpox". In 1864 he became physician to the Leeds General Infirmary, which

trade—both national and international—systems of husbandry, economics, industry and man-power.

There is a need for a detailed integrated report, representing all the interests concerned, on the requirements for the eradication of the disease.

Tuberculosis stands out as the major preventable animal disease in this country. Other diseases which now ravage our animals also require energetic attack at the earliest possible moment. One of the greatest contributions of a tuberculosis eradication scheme would be the stimulus and actual aid it would provide for the control of certain other diseases.

CONCLUSIONS

In this country, in spite of all that has been done, the quite extensive legislation of the last thirty years, the pioneer work done by the veterinary officers of the Ministry of Agriculture and Local Government Authorities, by the other scientists and by agriculturists, the present position with regard to tuberculosis control might be described as "the end of the beginning". Even so a very great deal has been accomplished. The scientific work to provide the essential knowledge has been done. A great wall of opposition has been broken down. The leaders of agricultural interests are clamouring for action. The veterinary service is organized, but at the present time it is numerically insufficient to undertake even the next stage which the Government is anxious to put into effect. Many more veterinary graduates are urgently required.

All milk except that from herds free from tuberculosis and the other important infective diseases should be pasteurized, and there appears to be little objection to the pasteurization of all milk.

An intensive educational programme, covering the requirements of both the workers in the cattle industry and the consumers of their products, should be undertaken. A suitable manual is required for the instruction of animal attendants.

Much could probably be done within the cattle industry to assist this control work. The marketing of cattle is not well organized with regard to the opportunity for the purchaser to select healthy animals. In existing circumstances it is difficult to control disease in the "Flying Herd".

Agriculture requires a long period of steady prosperity. Farm accommodation is often inadequate. Water supplies must be improved.

An "area" system for the eradication of tuberculosis should be started as soon as possible.

An inquiry into means of controlling tuberculosis and a detailed report embodying all the interests concerned in the problem are required.

The methods used in the eradication of tuberculosis will have a great influence in due course on action to be taken for the control of other infective diseases of farm animals.

being "Joseph Vance" and "Alice-for-Short". It happens that I know something of those years, for that wonderful old lady, Mrs. Russell Barrington, whom I knew well, lived next door to the Allbutts and was their close friend, often travelling abroad with them. It was the very heyday of Victorian prosperity, when Royal Academicians counted for something. It has often been alleged that George Eliot drew the portrait of Lydgate's Middlemarch from Clifford Allbutt in 1872, though obviously the portrait of Lydgate's wife is in sharp opposition to the real Mrs. Allbutt as she then was. George Eliot knew them well, but G. H. Lewes told Sir James Paget that she had never known a surgeon intimately. There is an obvious quibble here, for the novelist could easily turn a physician into a surgeon, and Allbutt himself was always a little self-conscious when taxed with the story. At any rate there is no doubt that he was the hero of Mrs. Russell Barrington's novel, *A St. Luke of the 19th Century*, for she told me so herself. She was the sister-in-law of Walter Bagehot, the well-known economist and writer, and knew all the literary and artistic celebrities of her day, which was a long one since she lived to well over 90. A dominant interesting personality, she acquired the nickname of the Duchess of Kensington, and held a circle in a house that was a museum, with a music room frescoed by Watts. In this pleasant setting Allbutt was very happy and when in 1892 the offer came of the Regius Chair at Cambridge it is not surprising that he hesitated before accepting new responsibilities. Little could he have realized that the greatest part of his career was yet to come and would occupy one-third of a century.

Sir George Paget, who had held the Chair with conspicuous success for twenty years, had died on January 29, 1892, at the age of 82. It had been usual for a resident to be appointed and now that more than half a century has elapsed there can be no harm done by saying that there were three physicians in residence, any one of whom would probably have been willing, to say the least, to take office. But to have appointed one of them would have roused fierce antagonism with the other two, while to have appointed any of them would have been distasteful to considerable, if different, sections of the University. So it is not surprising that it was hoped that the choice would fall elsewhere. Now of the six Regius Chairs the Crown had retained the right to appoint for three, Civil Law, Physic and Modern History, leaving Divinity, Greek and Hebrew to ordinary Boards of Electors. Sir Humphry Rolleston's statement that Dr. Alex. Hill, Master of Downing, was commissioned to sound Sir Andrew Clark as to his willingness to come, requires some expansion. True, a self-appointed junta meets and makes a recommendation to the Vice-Chancellor who conveys it via the Chancellor to the Crown advisers, but it by no means follows that this recommendation is acted upon. Ultimately the Prime Minister asks the individual selected if he is willing to have his name submitted to the Sovereign. So that it does not necessarily follow that Hill's invitation would have become operative, though Sir Andrew's eminence makes this highly probable. Anyhow he declined, as did Allbutt, whose name apparently had been suggested by Sir Michael Foster. Fortunately, Sir William Broadbent, on behalf of Her Majesty's advisers, succeeded in persuading him to accept. Here again Foster proved himself a supreme judge of man. It was the psychological moment for such an appointment. The medical school had achieved great internal success, and now there was a man who could make it equally successful externally, carrying its influence outside Cambridge to the world at large, for there was nothing parochial about his outlook.

Well do I remember his inaugural lecture given in May 1892. His handsome, dignified, well-groomed appearance made an instant appeal. Still more impressive was the substance of a lecture blending science with the humanities which gave me a new outlook. It was really a decisive influence in my life. Little did I dream then that forty years later it would fall to my lot to give the lecture on a similar occasion, though not, I fear, with such impressiveness. It is not easy to wear the giant's robe.

The coming in of a Regius Professor from outside Cambridge led to an unfortunate complication, for previous occupants of the Chair had been physicians to Addenbrooke's Hospital prior to appointment. I referred in my last paper to the Downing Chair of Medicine which was occupied at the time of Allbutt's appointment by Peter Wallwork Latham. He was specially learned in organic chemistry, making original observations and advancing interesting views. He had a large practice and was much beloved by his patients. Yet when it came to University matters his genial appearance proved to be entirely misleading, for he was a good harer and a bitter controversialist. The quarrel over his emoluments dragged on for some years. His contribution to the medical school may be summarized as throwing a spanner into the works whenever occasion offered!

A characteristic action of his followed Michael Foster's resignation from the Chair of Physiology in 1903. Since for more than thirty years Foster had laboured incessantly and most successfully to build up the modern Medical School at Cambridge, a proposal was made by Allbutt and others that an extraordinary salaried Professorship should be created for him as a kind of pension. Latham violently opposed this and actually issued a fly-sheet belittling Foster's services to the University. Consequently the project had to be dropped.

One can accordingly realize that an attempt to obtain rights at Addenbrooke's for

then had on its surgical staff Samuel Hey, Wheelhouse and Pridgin Teale junior; with the last-named he became closely associated. Up till then, Leeds had been more renowned for surgery than medicine, but he speedily rectified that. Lord Moynihan said that Allbutt and Teale were pioneers of team-work. A new building, the first in England on the pavilion principle, was erected in 1869, which greatly facilitated their co-operation. Allbutt held a large number of posts in the Medical School, and gradually acquired a large consulting practice, though he said for some years he was "politely postponed as too young for confidences". So he filled in his waiting time with many papers and reviews. As Sir Humphry Rolleston remarked, "a striking feature of his life's work was the persistent way in which he returned to and expanded any subject on which he wrote; this is well shown by the progressive development and scope of his writings on cardio-vascular and nervous diseases and medical history". In 1867 he introduced the clinical thermometer now in ordinary use. The one with which Wunderlich had made his pioneer observations was a foot long and required twenty-five minutes to register. In the same year his important paper on the significance of skin affections appeared. Then he turned his attention to nervous and mental diseases at the West and East Riding Asylum, the outcome of which appeared in his monograph on the ophthalmoscope, his description of syphilitic disease of the cerebral arteries, six years before Heubner's classical account and his paper on locomotor ataxy. Always an advocate of the use of the hands, he urged the drainage of empyemas and pericardial effusions which he had seen performed in Trousseau's Clinic and gastric lavage as practised by Kussmaul. He also popularized hypodermic medication, which, introduced by Rynd of Dublin in 1844, had attracted very little attention, and he urged, against opposition, the water-borne character of some typhoid epidemics.

In 1869 he married Susan England. They had no children, so they adopted a niece of hers. It was a singularly happy marriage; he told me that when he was away from home he wrote to his wife every day. She was a gracious hostess and shared all his interests; she survived him about twelve years and was well over 90 when she died.

Soon after his marriage, Allbutt was elected a member of the Alpine Club; he had always been an enthusiastic climber from the age of 14 and continued the practice to quite an advanced age. In one of his papers on overstrain of the heart he described how he brought on an attack of acute dilatation of the right ventricle by climbing and how he lay down and percussed out his own enlarged cardiac dullness. Professor Roy (who had a similar experience when, convalescent after typhoid, he had an unexpected call to an accident on the mountains) told me that so far from percussing out his heart, he thought he was going to die and felt no interest in scientific observation.

This was the period in which Allbutt advanced the view that tetanus toxin extended up the peripheral nerves to the central nervous system, but this, although now established, was rejected by a committee of the Pathological Society. His advocacy of cold baths in the treatment of hyperpyrexia was more successful. In 1876 his paper on *Mental Anxiety as a Cause of Granular Kidneys* proved the starting-point of his work on hyperpæsis which he continued for so many years. About this time he became a pioneer of the open-air treatment of tuberculosis—another subject in which he continued to take warm interest for the rest of his life. He also had some severe things to say about "brain forcing" at school, maintaining that precocity was gained at the cost of feeble maturity and early decay and that schoolmasters as a class were utterly unconscious of the existence of the science of physiology. Here then is a whole group of topics where his view was definitely in advance of contemporary thought. As in thought so in conduct, for in 1880, being scandalized by medical expert witnesses contradicting one another in Court, he persuaded those in Leeds to refuse to give evidence except after consultation between both sides, a proceeding highly commended by Mr. Justice Stephen.

As is well known he deplored the divorce between medicine and surgery and induced his colleague Pridgin Teale to introduce the operation for removal of tuberculous glands in the neck. I am old enough to remember the ghastly scars that disfigured so many necks before this advice was generally followed.

In March 1884, having been elected F.R.C.P. in the previous year, Allbutt delivered the Goulstonian Lectures on Visceral Neuroses in which among other things he castigated the prevalent attribution of many ailments in women to small uterine displacements that required continued treatment "except during the long vacation when the gynaecologist is grouse shooting or salmon fishing or leading the fashion in the Upper Engadine". There is no doubt that these lectures had a profound influence on the recognition of the abdominal expression of psychoneuroses. The next month he retired from the active staff at Leeds under the twenty-year rule, but that he was heavily engaged in extensive consulting practice is shown not only by a comparatively small literary output during the next five years but still more by his toying with the idea of retirement at the age of 53. Instead came an interlude of three years in the form of a Commissionership in Lunacy before he was to take up even more important work. Surprise has often been expressed at such an unexpected change, but his asylum work made him suitable for it and it proved acceptable to him. A smaller income was offset by lighter work. He settled at 3, Melbury Road, Kensington, amid an artistic coterie which included G. F. Watts, Lord Leighton, Burne-Jones, Luke Fildes, Marcus Stone and, I think, Frank Dicksee. There was also William de Morgan, brother of the mathematician, who after designing artistic tiles in the Pre-Raphaelite mode, took to writing novels, the best known

pital on the outskirts of Cambridge under the enthusiastic direction of the late Dr. Strangeways. Some years later the hospital beds had to be given up, but the research laboratory continues to do admirable work.

Believing as he did that one of the functions of a University is to teach students to think, he attached great importance to the theses presented for the degree of M.B. and tightened up the procedure. The history of university theses is of some interest. They had replaced the old mediæval "Disputations" in the eighteenth century. That there was abuse of the method is shown in Gunning's reminiscences. He tells of a man named Nicholson in the later part of that century, who used to wander up and down college staircases murmuring "Maps, maps for sale". But this merely cloaked his real mission, which was to act as an agent between candidates and needy dons who provided candidates with theses. His own commissions must have been lucrative for they enabled him to start a bookshop opposite the Senate House, which later was purchased by the Macmillan brothers before they embarked on their London venture. Then the business became Macmillan & Bowes, and is now familiar to us as Bowes & Bowes.

Gradually theses were abolished except for doctorates, for the M.B. and as an alternative procedure for the B.D. Allbutt attached great importance to the style in which the M.B. thesis was presented and was so impressed with the inability of candidates to write decent English that he published *Notes on the Composition of Scientific Papers*, illustrated by choice examples of English as it ought not to be written. As he neatly put it, his quotations were "given for the most part without acknowledgment, for obvious reasons". Indeed, latterly he seemed more concerned about the style than the matter of the thesis. Still his efforts to stem the tide of scientific jargon, masquerading under the title of medical literature, were much needed and were not without effect.

It was complained by graduands that the delay in obtaining their degree caused by the preparation of these theses handicapped them in competing for resident appointments against graduates of other universities, or those qualified by the Conjoint Board. Allbutt met this by securing that the Bachelorship of Surgery, only obtainable when the whole M.B., B.Chir. examination had been passed, should be a registrable qualification. It was also alleged that the whole thing was stultified by literary "ghosts" who wrote the theses. But the cross-examination of the candidates would soon reveal whether the work was substantially his own, some help not being objected to. I only once had reason to be suspicious, and that curiously enough was of an M.D. thesis by a distinguished dermatologist!

It was therefore a great regret to me when my successor induced the University to abolish the M.B. thesis. I regard it as a retrograde step for the following reasons. They gave the young graduand the task of working at a specific problem and presenting his results in due form; these could be discussed with and criticized by a senior man, which should be a help to him when he later embarked on the shoals of "medical literature". It made for good personal relations for every graduand to have a talk of half an hour or so with his Regius. I owed my first personal association with Clifford Allbutt to reading my thesis to him. It induced men to revive contact with their University and College by their having to come up to read their thesis and then take their degree in person, the whole forming a pleasing ritual which distinguishes a University from a mere examining body. Since theses were abolished an increasingly large proportion of men just take the degree by proxy. To the Regius Professor the system had, besides the opportunity of knowing something of each graduate personally, the advantage of finding out just which teachers were influencing the students in the teaching hospitals. I hope I may be pardoned this incursion into controversy, which is dictated by my loyalty to my great predecessor's ideas. His efforts to raise the standard of general education of medical men were unceasing. As he said in 1902: "I have had already to observe to my pain that the Cambridge medical student of to-day is by no means 'learned'; that too often he thinks loosely, and that he does not always write even the English of the gentlemen who do the fires and murders for country journals. On his Latinity I will discreetly keep silence." It may therefore surprise some that he took so leading a part in urging, at length successfully, the abolition of compulsory Greek at Cambridge, but as he said, "If we make Greek optional we can raise our standard of Latin" and he deprecated "the sterile methods of cramming little boys with the abstract propositions of grammatical pedagogues" as a preparation for later passing the Littlego. Allbutt's own distinction as a classical scholar was recognized by his becoming President of the Classical Association and was shown by his great book on *Greek Medicine in Rome*. When this Section was established here in 1912, Osler became President and Allbutt was one of the original Vice-Presidents. It was indeed a fortunate thing for British Medicine that during most of the first quarter of this century the Regius chairs at Oxford and Cambridge were held by men of such outstanding distinction as Osler and Allbutt, so similar in outlook, so complementary in temperament. Those of us who were present at the celebration here of Osler's 70th birthday will never forget the impressive dignity and charm with which Allbutt presented the *Festschrift* to him, nor Osler's beautiful and touching reply, in the course of which he said: "To you, Sir Clifford, in fuller measure than to anyone in our generation has been given a rare privilege; to you when young, the old listened as eagerly as do now, when old, the young." It was indeed that universality of appeal which was Allbutt's great source of influence. In a sense, apart from the handicap of deafness, he never, even physically, seemed to grow old until quite shortly before his death. He could make humorous references to his years such as "that state of mind which seems mellow wisdom to its owner, but appears to the younger generation as senile obstinacy". On another occasion he said that while demonstrating

the Regius Professor met with strong opposition from the same quarter. Latham was credited with saying in the best style of Victorian melodrama that Allbutt would only enter the wards over his dead body. This tragedy was avoided by his resignation from the staff in 1899, and a *modus vivendi* was then quickly established between the University and the Hospital, giving the Regius Professor *ex officio* rights to beds and to teaching in the wards.

Allbutt made good use, however, of his eight years' exclusion from hospital work for he employed them in the production of his *System of Medicine*, a really great literary and scientific work. The introduction is an exposition of his medical philosophy, in which he maintained that there is no more a standard pattern of disease than a standard pattern of man. Disease is not an entity, but a reaction of the whole individual. He disliked the label of "types" though he had to admit their adoption in a *System of Medicine*. This essay was, to the regret of many readers, deleted from the second edition in which Sir Humphry Rölleston collaborated. Possibly the author considered his view, previously regarded as revolutionary, was now accepted and therefore need not be repeated. Fourteen other articles appeared from his pen and I would specially call attention to those on digestive neuroses and on drug addiction as admirable examples of real medical literature.

The last decade of the nineteenth century in which Allbutt took office was indeed an extraordinary one in the history of medical progress. It saw the beginning of endocrine therapy, the first antitoxins, the discovery of X-rays and radium, the start of clinical pathology. To those of us who were students then it seemed, as it had a century before to Wordsworth—

"Bliss was it in that dawn to be alive

But to be young was very heaven."

It wasn't really, but the kindly finger of Time has rubbed out the unpleasant memories and left only the recollection of the thrills and excitement as discovery followed on discovery. Allbutt was always alive to such new developments even to an advanced age. As an instance of this outlook I may quote his remark that during his lifetime medicine had "not so much changed as transformed: a generation ago the doctor was an observer and a naturalist, and by practice mainly an empiric; now medicine was being reconstructed" on a more scientific basis. In the same spirit he kindly wrote the preface for an *Encyclopaedia of Medical Treatment*. I edited in conjunction with the late Keogh Murphy in 1915. After a remarkable résumé of the progress of medicine he said: "On a mountain in Switzerland, far away from books and papers, I have ventured to make this sketch of the new Therapeutics . . . I have rambled at large among the discoveries which have awakened my own enthusiasm . . . What a joy it would be to start from the present and, with these new visions, to begin it all over again!" A striking pronouncement from a man who had just entered his eightieth year. The late Dr. W. E. Dixon, Reader in Pharmacology in the University, bore testimony to this extraordinary freshness of mind when he told me within a year of Allbutt's death that he would still discuss the work going on in the Department and even suggest new experiments.

The breadth and forward direction of his outlook was manifested in many other ways. Thus for years he strongly advocated the study of comparative pathology and was instrumental in founding the Section for this subject in this Society, becoming, appropriately enough, its first President. Always an advocate of fresh-air treatment (though as he put it "not treatment by hurricane") in tuberculosis, he was actively interested in Varrier-Jones' scheme for Village Settlements for tuberculous subjects. At the outbreak of the last war, Varrier-Jones, who was rejected for the Army on account of his heart, that heart which was to fail him so tragically twenty-seven years later, undertook the duties of the Cambridge Tuberculosis Officer, who had joined up. He soon realized that as long as patients were returned to their old environment they were doomed to relapse. So he accordingly ventured to open a small settlement in the neighbouring village of Bourn, with such success that in 1918 he was able to transfer it to much larger quarters at Papworth. Allbutt warmly supported the scheme and became the first President of the Settlement, remaining throughout his life a valued helper and adviser. Much of the success of this plan of rehabilitating patients into suitable industries, while they lived with their families in suitable cottages, was due, as Varrier-Jones declared, to his wise counsel and influential advocacy. In the same way he actively supported Sir Henry Gauvain's work at Alton for surgical tuberculosis.

Then he was always urging the change from the asylum conception to that of the mental hospital, with facilities for investigation and research, the importance of which is now generally admitted. Towards that end he played a large part in establishing the Diploma in Psychological Medicine at Cambridge. It might be thought he was inconsistent in opposing psycho-analysis so vehemently, but it should be remembered this was at a time when its disciples, medical and lay, were indulging in great extremes. It had become a fashion for undergraduates to psycho-analyse one another, often with deplorable results.

Many of the changes he advocated in the medical curriculum are now being brought forward as new ideas forty years later. With the financial aid of his friend Dr. (later Sir) Charles Brown of Preston, he was largely instrumental in establishing a Research Hos-

pital on the outskirts of Cambridge under the enthusiastic direction of the late Dr. Strangeways. Some years later the hospital beds had to be given up, but the research laboratory continues to do admirable work.

Believing as he did that one of the functions of a University is to teach students to think, he attached great importance to the theses presented for the degree of M.B. and tightened up the procedure. The history of university theses is of some interest. They had replaced the old mediæval "Disputations" in the eighteenth century. That there was abuse of the method is shown in Gunning's reminiscences. He tells of a man named Nicholson in the later part of that century, who used to wander up and down college staircases murmuring "Maps, maps for sale". But this merely cloaked his real mission, which was to act as an agent between candidates and needy dons who provided candidates with theses. His own commissions must have been lucrative for they enabled him to start a bookshop opposite the Senate House, which later was purchased by the Macmillan brothers before they embarked on their London venture. Then the business became Macmillan & Bowes, and is now familiar to us as Bowes & Bowes.

Gradually theses were abolished except for doctorates, for the M.B. and as an alternative procedure for the B.D. Allbutt attached great importance to the style in which the M.B. thesis was presented and was so impressed with the inability of candidates to write decent English that he published *Notes on the Composition of Scientific Papers*, illustrated by choice examples of English as it ought not to be written. As he neatly put it, his quotations were "given for the most part without acknowledgment, for obvious reasons". Indeed, latterly he seemed more concerned about the style than the matter of the thesis. Still his efforts to stem the tide of scientific jargon, masquerading under the title of medical literature, were much needed and were not without effect.

It was complained by graduands that the delay in obtaining their degree caused by the preparation of these theses handicapped them in competing for resident appointments against graduates of other universities, or those qualified by the Conjoint Board. Allbutt met this by securing that the Bachelorship of Surgery, only obtainable when the whole M.B., B.Chir. examination had been passed, should be a registrable qualification. It was also alleged that the whole thing was stultified by literary "ghosts" who wrote the theses. But the cross-examination of the candidates would soon reveal whether the work was substantially his own, some help not being objected to. I only once had reason to be suspicious, and that curiously enough was of an M.D. thesis by a distinguished dermatologist!

It was therefore a great regret to me when my successor induced the University to abolish the M.B. thesis. I regard it as a retrograde step for the following reasons. They gave the young graduand the task of working at a specific problem and presenting his results in due form; these could be discussed with and criticized by a senior man, which should be a help to him when he later embarked on the shoals of "medical literature". It made for good personal relations for every graduand to have a talk of half an hour or so with his Regius. I owed my first personal association with Clifford Allbutt to reading my thesis to him. It induced men to revive contact with their University and College by their having to come up to read their thesis and then take their degree in person, the whole forming a pleasing ritual which distinguishes a University from a mere examining body. Since theses were abolished an increasingly large proportion of men just take the degree by proxy. To the Regius Professor the system had, besides the opportunity of knowing something of each graduate personally, the advantage of finding out just which teachers were influencing the students in the teaching hospitals. I hope I may be pardoned this incursion into controversy, which is dictated by my loyalty to my great predecessor's ideas. His efforts to raise the standard of general education of medical men were unceasing. As he said in 1902: "I have had already to observe to my pain that the Cambridge medical student of to-day is by no means 'learned'; that too often he thinks loosely, and that he does not always write even the English of the gentlemen who do the fires and murders for country journals. On his Latinity I will discreetly keep silence." It may therefore surprise some that he took so leading a part in urging, at length successfully, the abolition of compulsory Greek at Cambridge, but as he said, "If we make Greek optional we can raise our standard of Latin" and he deprecated "the sterile methods of cramming little boys with the abstract propositions of grammatical pedagogues" as a preparation for later passing the Littlego. Allbutt's own distinction as a classical scholar was recognized by his becoming President of the Classical Association and was shown by his great book on *Greek Medicine in Rome*. When this Section was established here in 1912, Osler became President and Allbutt was one of the original Vice-Presidents. It was indeed a fortunate thing for British Medicine that during most of the first quarter of this century the Regius chairs at Oxford and Cambridge were held by men of such outstanding distinction as Osler and Allbutt, so similar in outlook, so complementary in temperament. Those of us who were present at the celebration here of Osler's 70th birthday will never forget the impressive dignity and charm with which Allbutt presented the *Festschrift* to him, nor Osler's beautiful and touching reply, in the course of which he said: "To you, Sir Clifford, in fuller measure than to anyone in our generation has been given a rare privilege: to you when young, the old listened as eagerly as do now, when old, the young." It was indeed that universality of appeal which was Allbutt's great source of influence. In a sense, apart from the handicap of deafness, he never, even physically, seemed to grow old until quite shortly before his death. He could make humorous references to his years such as "that state of mind which seems mellow wisdom to its owner, but appears to the younger generation as senile obstinacy". On another occasion he said that while demonstrating

on a patient aged 40 he became conscious of a misunderstanding between himself and his students. He finally traced it to the fact that he was regarding someone as in the prime of life who to undergraduates was already in the sere and yellow leaf. In this playful humour he kept in touch with old and young alike.

It would be a misfortune for his memory if Orpen's portrait of him in the Fitzwilliam Museum should come to be regarded as an authentic likeness, for it is almost a caricature. When taxed with this Orpen replied, "Well, to tell the truth, I wasn't interested in the old man"; which is a criticism of the artist rather than of his subject.

It would be tedious to detail all the honours which fell thick on him, and all the honorary degrees conferred. It is somewhat surprising that he did not become a K.C.B. until he had been Regius Professor for fifteen years, but, as a matter of fact, he had declined a knighthood even before he was appointed to Cambridge. He had little desire for such honours, but I think he was gratified by the chorus of congratulations he received on that occasion, and also when he was made a Privy Councillor in 1920. His election to the Royal Society, now so rare for a physician, should also be mentioned.

It was delightful to enjoy his and Lady Allbutt's hospitality at St. Rhadegund's. The house and grounds are now divided up, for, alas, those spacious days are a thing of the past. After dinner his guests would discreetly retire into the garden to smoke, as for some unknown reason, tobacco fumes produced troublesome extrasystoles in their host. He had indeed several curious drug idiosyncrasies.

It was extraordinary how he managed to keep up with the doings of his old alumni. If one of them did a good piece of work he would probably receive a letter in a curious script which when deciphered would prove to be a charmingly phrased note of appreciation from his Regius Professor. Naturally, as one so interested in the history of medicine as he, Allbutt highly valued the antiquity of his office and always made use of the arms granted by Queen Elizabeth in 1590 to the Regius Professors of Physic in perpetuity. He incorporated them in his book plate; and among other cherished emblems of his office were the seal, surmounted by a small silver replica of Gian Bologna's Flying Mercury, and the actual Regius Chair of pre-Chippendale design, which together with his doctor's scarlet gown are handed on to his successors. A gesture, surely, deeply appreciated by all who value tradition and continuity.

He was a cultured scholar-physician, of a type becoming rare in these disturbed and bustling days. His fastidious taste in literature made him a meticulous critic of his own writings. They read so smoothly and pleasantly, and this he regarded as so important, that he always wrote three drafts before finally sending them to the Press. He had an almost uncanny faculty for winnowing the wheat from the chaff in the mass of new work and ideas constantly poured out.

Born before the introduction of anesthetics he had seen changes in medicine which were unrivalled and not likely to be surpassed in the future. One thing he continued to lament—the divorce of medicine and surgery. "How long", he asked, "are we to go on, as by a Solomon's Schism, cutting maladies into halves and distributing one moiety to one professor, the other to another without laughter or tears?" It is to be feared that this desirable aim is, in an age of increasing specialism, even more visionary than when he spoke.

By the force of his remarkable personality Allbutt certainly raised the status of the Regius Chair higher than it had ever been. I should like to quote some of Sir Humphry Rolleston's eloquent words about his predecessor. "Aristocratic in appearance and courtly in manner he was the most approachable of men, modest almost to a fault as towards his own attainments, enthusiastic in praise of his colleagues and juniors, and so tolerant that he seemed never to notice any small shortcomings." No wonder he was admired and beloved.

His philosophic attitude was exemplified in a letter to me a few years before his death, in which he said he knew rather than felt he was approaching the end of a long life. The last time I dined with him he said: "It isn't dying I mind; what I fear is incapacity." He was spared that, for apart from a heart attack a few months before his death, he was in very much his usual health until the fatal seizure which only lasted ten minutes. This was in the early morning of February 22, 1925, when he was nearly 89. The ultimate residue of his estate he left to Caius College for the establishment of Clifford Allbutt Fellowships for medical research.

Allbutt was a deeply religious man. A member of the Church of England, he was greatly attracted towards the Society of Friends, but as he said: "How can I leave a church in which I was born, baptized and married, with which all my life has been inextricably bound up—tendrils everywhere." It was well said of him that "among the religious he stood for scientific method; among scientists for religious faith". He preached not infrequently and sometimes in St. Edward's Church, Cambridge. Founded by the Franciscans, this tiny church with its lovely columns stands in a backwater of ancient peace, though close to the busy market place. It seems a singularly appropriate setting for one whose inward serenity remained undisturbed by close contact with outward affairs. As Archdeacon J. W. Hunkin, now the Bishop of Truro, said in his memorial sermon, "no man ever came nearer the ideal of what a Regius Professor of Physic should be in a University".

"Ripeness is All."

Section of Dermatology

President—SYDNEY THOMSON, M.D.

[October 18, 1945]

Angioma Serpiginosum (Crocker).—J. E. M. WIGLEY, M.B.

Miss R. M., aged 35.

The original area on the right upper arm was first noticed about twenty years ago. This has spread to its present distribution within the last four to five years and new lesions are still appearing. None of the lesions is known to have disappeared spontaneously. There are no symptoms associated with it, but the patient is distressed by its appearance. Her general health and bodily functions are unaffected. She does not take any drugs, such as adalin, &c.

The distribution is shown in fig. 1 and will be seen on the arms, trunk and thighs, being more marked on the right side than on the left. Note the sharp line of demarcation down the mid-trunk. The essential appearance is well shown in fig. 2. It consists of a reticular and partly serpiginous telangiectasia of varying intensity, dotted over with bright red "cayenne pepper" spots, some of which feel raised above the surface but do not disappear on pressure. There is no pigmentation visible. No scaling or definite atrophy of the skin was obvious. Two rectangular areas, shown in the photograph, were treated with a radium plaque about two years ago, where it will be seen that the lesions have almost disappeared.

Histology.—Sections were made and examined by Dr. Freudenthal who writes that the essential changes were a number of very considerably dilated capillary vessels in the papillary body, mostly filled with red blood corpuscles, and that there was hardly any cellular infiltrate. This is in contrast to the picture usually seen in Schamberg's disease and agrees well with the diagnosis of angioma serpiginosum.

It appears that the case is typical of that described by Sir Jonathan Hutchinson ("A Peculiar Form of Serpiginous and Infective Nævoid Disease", *Arch. Surg.*, 1890, 1, Part 9). The name angioma serpiginosum was later given to the condition by Radcliffe Crocker ("Angioma Serpiginosum". *Diseases of the Skin*, 1905, 2, 906).

Is it the view of members that thorium X would be the best method of treatment?

FIG. 1.

Angioma serpiginosum. (Photographs by A. C. Roxburgh, M.D.)

FIG. 2.

Dr. H. C. Semon: Thorium X is well worthy of trial, the more so because there is no other treatment available.

Dr. F. Parkes Weber: I do not see any other way of treating this case than by making the small blood-vessels atrophy. This is apparently what has happened to the area on one shoulder which is now free as a result of previous radium exposure. These cases vary in degree. There may be very slight cases with just a line of red or cayenne pepper spots. I had two cases together many years ago (F. P. Weber, *Proc. R. Soc. Med.*, 1927, 20, Sect. Derm., 107) and spontaneous involution has taken place since then in at least one of the two cases. The condition is certainly developmental, but apparently seldom if ever familial (see, however, Williams, *Arch. Derm. Syph.*, Chicago, 1924, 9, 783).

Dr. W. N. Goldsmith: I have had success with ultraviolet rays.

Poikiloderma Atrophicans Vascularis.—H. MACCORMAC, C.B.E., M.D., and J. E. M. WIGLEY, M.B.

H. T., a man aged 41 years, a Polish national, was seen by one of us (H. MacC.) on October 3, 1945. He stated that the eruption first appeared on the flexural regions of the arms at 19 years of age and has gradually extended and continued up to the present time. The condition worsened last year, when he was admitted into Ashridge E.M.S. Hospital under Dr. Wigley. The patient is an unusually well-built man without any trace of muscular affection. He has been treated for a duodenal ulcer and has spent during the war six months in India. His blood-count is normal and the blood Bordet-Wassermann reaction is negative. Temperamentally he is highly-strung which may account for the complaint of cramp in the arms, a symptom elicited by a leading question.

The eruption is widely distributed as follows: the skin of the cheeks is lightly pigmented and possibly atrophic; on the neck there is a collar of reticular pigmentation, while over the arms and breasts pigmentation, dilated vessels, desquamative and finely atrophic skin are observed. In the region of the groins there is a reticular pigmentation similar to that seen on the neck, while over the thighs, fading as it extends downwards on to the legs, the skin is bright reddish-blue, with atrophy, slight scaling, and marked capillary dilatation. The resemblance to X-ray dermatitis which has been often remarked upon is well shown in this case.

A number of examples of this rare disease process have been exhibited at the Section during the last fifteen years and have been fully reported. Until the valuable and illuminating paper by G. B. Dowling and W. Freudenthal (*Brit. J. Derm.*, 1938, 50, 519) appeared, it would seem that dermatomyositis and poikiloderma atrophicans vascularis were often confused both here and abroad, and dermatology owes a debt to these authors for giving us the measure, clinical and histological, by which these two conditions can be distinguished. On this evidence it would seem that the original case described by Petges and Cléjat should now be classified as dermatomyositis. The histological differences have been summarized by Dowling and Freudenthal as follows: in poikiloderma the changes are characteristic of inflammation, in dermatomyositis they are degenerative; and the inflammatory character of the reactions in a section from the case now under consideration bears this out.

Dr. F. W. Jacobson: Dr. Mitchell Heggs and I in a case similar to this some years before the war carried out treatment by thorium X (*Proc. R. Soc. Med.*, 1936, 29, 717-720 (Sect. Derm., 57)). I was able to follow up the case for years. Thorium X was given once a fortnight—1,500 electrostatic units. The irritation disappeared completely, the pigmentation also disappeared. The atrophic changes were not altered. From this point of view it should be tried in this case as well.

Dr. H. MacCormac: Is it meant that the whole affected area should be painted with thorium X, i.e. most of the body surface?

Dr. F. W. Jacobson: Yes, it takes a long time to show a good result.

Dr. H. MacCormac: What is the effect on the blood?

Dr. F. W. Jacobson: No effect.

Pityriasis Lichenoides et Varioliformis.—ALICE CARLETON, M.D.

Male child aged 3, with a diffuse rash on the body and limbs, consisting of pinkish-brown macules with slight scaling, crusted vesico-papules about $\frac{1}{8}$ inch in diameter, pitted scars and patches of pale atrophic skin on the forearms. The rash and blood-count are normal. He has carious incisors and enlarged cervical and axillary glands. The condition has existed for a year. In view of the duration of so many of these cases, is the term "acuta", which is generally added to the title, a suitable one?

Dr. G. B. Dowling: A case which I presented at a recent meeting pursued a course of about three months from beginning to end.

Dr. H. W. Barber: I agree with Dr. Dowling. I have seen one case—the wife of a doctor—in which the eruption disappeared in about a month. She had injections of gold, but

I cannot say whether they had any effect. The duration of the disease admittedly varies greatly. The same is true of the cases without varioliform lesions, of which Dr. MacCormac first showed an example at this Section.

Dr. A. C. Roxburgh: I had a case in a soldier who came to Bart's during the war. He had had the condition all through the war and it had been possible to keep it in check to some extent by ultraviolet light, but it did not entirely clear up.

‡ **Kaposi's Angiosarcoma.**—ELIZABETH HUNT, M.D.

Married man, aged 47. First became aware of a red spot on the skin of his back two years ago. Since then it has gradually developed into the present condition. It has never caused him any discomfort, except for slight irritation at times. He has no clear recollection of ever having had any injury at the site.

The area now affected extends laterally to the left for about 10 to 12 inches from the lower dorsal and lumbar spines.

The lesions are raised indurated tumours, the surfaces of which are elephantiasic in appearance or in some parts resemble hæmangiomas.

At the borders of the area, narrow red inflammatory-looking curved lines are present, which are infiltrated.

Pathological Report (Dr. Janes):

W.R. negative.

Corrected sedimentation rate 8 mm.

Hæmoglobin 110%

R.B.C. 5,510,000 per c.mm.

C.I. 1.0.

W.B.C. 7,400 per c.mm.

Differential count:

Polys. 66%

Lymphos. 19%

Monos. 13%

Eosinos. 2%

Histology.—There is a dense proliferation of spindle cells in the corium around small capillary-like spaces, accompanied by patchy lymphocytic infiltration. The overlying epithelium is not involved in the process. I feel that the spindle cells are vasoformative in origin and the presence of mitoses as well as the general features suggest an angiosarcomatous structure. This conclusion raises the question of Kaposi's disease.

Sections stained for iron showed no iron present.

Dr. H. W. Barber: I showed a case of this kind some years ago in an elderly man. There is always a discussion as to whether these cases are mycosis fungoides of the "d'émblée" type, or true sarcomata. My own opinion is that they are sarcomata. The serpiginous and infiltrated erythematous lesions surrounding the tumours are an interesting feature and recall those seen in the so-called "carcinoma erysipelatoides".

Dr. F. Parkes Weber: Are there not some cases in which lines like those in the present case referred to by Dr. Barber occur on the skin in patterns? I think I have seen illustrations described as pre-mycotic cases, but of course pre-mycotic eruptions, if really infiltrated, are cases of true mycosis fungoides, and the mass in the present case may be mycosis fungoides d'émblée.

Dr. G. Dowling: I doubt whether it is always possible clinically to distinguish between mycosis fungoides a tumeur d'émblée and sarcoma of the skin. A certain histological picture belongs to mycosis fungoides and another to sarcoma. I do not believe either that it is possible to estimate the prognosis; some may be controlled for years by X-ray, while others pursue a rapidly malignant course with involvement of organs or bone.

Dr. A. C. Roxburgh: I showed a case very much like this to the British Association of Dermatology in 1942. I had shown it as mycosis fungoides, but it was taken clinically by most members to be probably a sarcoma. A section was made, and it proved to be some form of sarcoma. I turned the patient over to the X-ray therapy department at Bart's and they gave him treatment. He has kept well since.

Dr. H. W. Barber: Have members seen the lesions in these cases break down ultimately? The case, to which I have just referred, was treated with X-rays over a long period, and some of the nodules broke down and ulcerated.

The President: I have seen one case break down—histologically it was most like a fibrosarcoma.

Dr. C. H. Whittle: Does the response to X-rays help in distinguishing between mycosis fungoides and sarcoma?

The President: These merging types are both very radio-sensitive.

Dr. W. N. Goldsmith: We have to consider the significance not only of responsiveness to X-rays, but also of spontaneous disappearance. Some cases that begin like mycosis fungoides clinically and histologically, the lesions of which from time to time vanish of their own accord, develop later into a condition indistinguishable from sarcoma, which is steadily progressive and fatal. Pathologists as well as clinicians may have difficulty in drawing the line between mycosis fungoides and sarcoma; and analogously, as Ferguson Smith has pointed out (1934, *Brit. J. Derm.*, 46, 267), even lesions with the histology of prickle-celled carcinoma may heal spontaneously.

Dr. W. Freudenthal: I agree with Dr. Goldsmith that sometimes neither clinically nor histologically are we able to draw a line between mycosis fungoides and this kind of sarcoma.

Benign Lymphogranuloma of Schaumann with Apparent Involvement of the Anterior Pituitary.—H. W. BARRER, M.B.

Mr. O. S., medical student. Native of Honduras. Aged 28. Resident in this country for over six years. He was referred to me by Dr. Mumford in January 1945, after having been under his and Dr. Savarard's care for some time. He had been treated with injections of gold and sodium morrhuate without apparent improvement of any note, but the amount given of both appears to have been small.

This case is chiefly of interest in that the patient at one time presented a syndrome of symptoms indicative of involvement of the anterior part of the pituitary gland, presumably owing to infiltration by a nodule of sarcoidosis.

There is nothing of note in his previous medical history, except that he has had benign tertian malaria. Both his parents and three sisters are alive and well.

Résumé of history of the sarcoidosis.—Onset (probably about five years ago): The first symptom was swelling and tenderness of the terminal part of the right ring finger. Subsequent X-ray examination showed that the greater part of the terminal phalanx had disappeared. He was advised to go away for three months, and on his return another radiograph revealed that there had been regeneration of bone, but the finger remained swollen and tender.

During the following winter, acute and very painful swelling, lasting about ten days, of finger- and toe-joints occurred, but only one joint was affected at a time. A diagnosis of arthritis was made, and injections of gold were given, but these afforded only temporary improvement, and the condition of the fingers and toes deteriorated every winter.

At the beginning of 1944 an increasing asthenia was experienced and shortly afterwards the first lesions of the skin appeared, first on the forehead, and later on the cheeks, eyelids, nose, and lobes of the ears. The appearance of the nodules on the nose was preceded by intense itching and vascular dilatation.

Asthenia: Slight at the onset, became severe at the beginning of 1944, so that he could hardly rise in the morning and was utterly exhausted by the end of the day. By September 1944 he felt too ill to leave his house. With the asthenia there developed almost complete loss of appetite, and of libido and sexual potency.

Loss of body hair: In July 1944 he observed the disappearance of coarse hair from the arms, legs and axillæ, and marked thinning of the hair in the pubic region.

COMMENT.—I first saw the patient 4.1.45 and he was admitted to Nuffield House, Guy's Hospital 7.2.45. The main features then were:

Skin: Large numbers of sarcoid lesions of various types on the forehead, cheeks, nose and ears. The nose presented the appearance of lupus pernio. One lesion on the abdomen and one on the left leg.

Bones and articular structures: The terminal and first interphalangeal joint-areas of all the fingers and both thumbs were involved. The toes were similarly affected.

Glands of considerable size were palpable in the cervical region, and the epitrochlear ones were noticeably large.

Body hair: No coarse hair on the arms, legs, and in the axillæ. Pubic hair scanty.

The skin as a whole was dry, and presented the "flaky" appearance seen in Simmonds' disease. There was very marked keratosis pilaris.

Blood-pressure varied from 90/60 to 100/70.

Dr. Bishop saw the patient with me and agreed that the symptoms suggested involvement of the anterior part of the pituitary gland. There has also been evidence of diabetes insipidus, which has been recorded in this disease by Léné, Launay et Séc (*Société Méd. des Hôp. de Paris*, 1935, 1137), by Tillgren (*Brit. J. Derm.*, 1933, 47, 223) and by Snapper, in that he had marked polydipsia and polyuria, which developed in 1944 at the same time as his loss of appetite, and continued until soon after he entered hospital.

The reports on the various investigations are appended.

Report on the eyes by Mr. Frank Law: There is evidence of a low-grade chronic cyclitis in the form of large keratitis punctata spots; these are of the greasy, "mutton-fat" variety, commonly associated with a tuberculous infection of the eye. Some secondary vitreous haze.

Treatment.—Dr. Bishop agreed that replacement therapy should be attempted for the pituitary deficiency, and he implanted under the skin 200 mg. of desoxycorticosterone acetate and 600 mg. of testosterone on 24.2.45.

Dried thyroid 1-1½ grains daily was taken from 25.4.45 to 7.6.45.

For the sarcoidosis I decided to try the effect of stovarsol: 6 grains were given after breakfast and 4 grains in the evening for three successive days, followed by three days' interval. He had 13 courses of stovarsol between 2.3.45 and 14.6.45. He also received two blood transfusions, a course of intramuscular injections of plexan, and iron by mouth; and for a while exposures of ultraviolet light.

A second implantation of desoxycorticosterone acetate and testosterone was also made. He has been away from hospital for short periods, but has now been readmitted.

Result of treatment.—There has been a marked improvement in the sarcoidosis. Many of the lesions on the face have cleared up, leaving stains. Those of the nose and ears have greatly diminished in size, and the fingers and toes are less swollen and congested.

As regards the involvement of the anterior pituitary, the patient has recovered his vigour and appetite, and coarse hair has regrown on the limbs and pubic region and in the axillae. The general texture of the skin is now normal and the blood-pressure is 110/70.

—I doubt whether the improvement is entirely due to replacement therapy. It seems more likely that the pituitary gland has recovered its function—at any rate to some extent.

Radiograms.—Chest: The hilar shadows are large and dense and there is a calcified focus on the right with a thickened right interlobar septum. There is in addition an increase of striation to the right upper lobe and while no definite focus is noted the presence of active tubercle cannot be excluded.

Skull: The pituitary fossa is rather shallow but of normal A.P. length. The posterior clinoids are larger than normal with a thin line of calcification connecting them to the anterior clinoids. There is in addition some calcification of the clino-petrous ligament.

Bones: Marked decalcification of phalanges of the feet and hands, with areas of complete bony absorption and some narrowing of interphalangeal joints.

Serum proteins: Total, and A/G ratio normal.

Serum sodium and chloride: Both low at first. Improved after additional salt in diet for a while, but were low again 12.10.45.

Urine: Sp. gr. 1006, pH 6.0. Nil abnormal found.

Blood: Numerous blood-counts and estimations of the B.S.R. were made. The main features were polynuclear leucopenia; eosinophilia, which varied greatly (highest 15%); moderate diminution of hæmoglobin, which improved after blood-transfusions; and moderate increase of B.S.R.

? **Reticulosis.**—LOUIS FORMAN, M.D.

Married woman, aged 30. Ten months ago was delivered of a macerated fœtus (6 months). Two years' history of grouped papules over abdomen, upper thighs, and fronts of shoulders. The central brown papule, 3-4 mm. in diameter, tended to necrose in the centre, and was surrounded by smaller, flat, brown papules.

Section of a larger papule shows an infiltration in the cutis consisting of cells with irregular large nuclei and and some giant cells: strongly suggestive of a reticulosis.

Blood-count (September 20, 1945).—Hb. 67%; R.B.C. 3,960,000; W.B.C. 5,300. Polys. 37%; lymphos. 58.5%; monos. 4%; eosinos. 0.5%.

Favus.—H. J. WALLACE, M.D.

Girl, aged 16, with a history of recurrent sepsis and crusting in the scalp for the past three years. No diagnosis was made originally, though some of the lesions bore some resemblance to psoriasis. Recently atrophy and scutula appeared. The condition began when she was evacuated to Berkhamsted. Four other young children are at home, with no evidence of infection. Fungus is present in the hair on microscopical examination and a culture is being made.

The President: These cases of favus are extremely interesting and I feel reasonably certain that twenty or twenty-five years ago we did not have cases of this type at all, yet there is no doubt that now we are all beginning to see these cases which suggest psoriasis, so that at first the possibility of fungus infection does not occur to one.

Dr. C. H. Whittle: I collected notes of cases which various members had shown before and mentioned them with my own three cases at the meeting of the British Association of Dermatology last July. My impression was that quite a number of them had recovered. In discussing diagnosis and treatment with Dr. A. M. H. Gray, I learnt that he had had

Dr. W. Freudenthal: I agree with Dr. Goldsmith that sometimes neither clinically nor histologically are we able to draw a line between mycosis fungoides and this kind of sarcoma.

Benign Lymphogranuloma of Schaumann with Apparent Involvement of the Anterior Pituitary.—H. W. BARBER, M.B.

Mr. O. S., medical student. Native of Honduras. Aged 28. Resident in this country for over six years. He was referred to me by Dr. Mumford in January 1945, after having been under his and Dr. Savatard's care for some time. He had been treated with injections of gold and sodium morrhuate without apparent improvement of any note, but the amount given of both appears to have been small.

This case is chiefly of interest in that the patient at one time presented a syndrome of symptoms indicative of involvement of the anterior part of the pituitary gland, presumably owing to infiltration by a nodule of sarcoidosis.

There is nothing of note in his previous medical history, except that he has had benign tertian malaria. Both his parents and three sisters are alive and well.

Résumé of history of the sarcoidosis.—Onset (probably about five years ago): The first symptom was swelling and tenderness of the terminal part of the right ring finger. Subsequent X-ray examination showed that the greater part of the terminal phalanx had disappeared. He was advised to go away for three months, and on his return another radiograph revealed that there had been regeneration of bone, but the finger remained swollen and tender.

During the following winter, acute and very painful swelling, lasting about ten days, of finger- and toe-joints occurred, but only one joint was affected at a time. A diagnosis of arthritis was made, and injections of gold were given, but these afforded only temporary improvement, and the condition of the fingers and toes deteriorated every winter.

At the beginning of 1944 an increasing asthenia was experienced and shortly afterwards the first lesions of the skin appeared, first on the forehead, and later on the cheeks, eyelids, nose, and lobes of the ears. The appearance of the nodules on the nose was preceded by intense itching and vascular dilatation.

Asthenia: Slight at the onset, became severe at the beginning of 1944, so that he could hardly rise in the morning and was utterly exhausted by the end of the day. By September 1944 he felt too ill to leave his house. With the asthenia there developed almost complete loss of appetite, and of libido and sexual potency.

Loss of body hair: In July 1944 he observed the disappearance of coarse hair from the arms, legs and axillæ, and marked thinning of the hair in the pubic region.

COMMENT.—I first saw the patient 4.1.45 and he was admitted to Nuffield House, Guy's Hospital 7.2.45. The main features then were:

Skin: Large numbers of sarcoid lesions of various types on the forehead, cheeks, nose and ears. The nose presented the appearance of lupus pernio. One lesion on the abdomen and one on the left leg.

Bones and articular structures: The terminal and first interphalangeal joint-areas of all the fingers and both thumbs were involved. The toes were similarly affected.

Glands of considerable size were palpable in the cervical region, and the epitrochlear ones were noticeably large.

Body hair: No coarse hair on the arms, legs, and in the axillæ. Pubic hair scanty.

The skin as a whole was dry, and presented the "flaky" appearance seen in Simmonds' disease. There was very marked keratosis pilaris.

Blood-pressure varied from 90/60 to 100/70.

Dr. Bishop saw the patient with me and agreed that the symptoms suggested involvement of the anterior part of the pituitary gland. There has also been evidence of diabetes insipidus, which has been recorded in this disease by Léné, Launay et Sée (*Société Méd. des Hôp. de Paris*, 1935, 1137), by Tillgren (*Brit. J. Derm.*, 1933, 47, 223) and by Snapper, in that he had marked polydipsia and polyuria, which developed in 1944 at the same time as his loss of appetite, and continued until soon after he entered hospital.

The reports on the various investigations are appended.

Report on the eyes by Mr. Frank Law: There is evidence of a low-grade chronic cyclitis in the form of large keratitis punctata spots; these are of the greasy, "mutton-fat" variety, commonly associated with a tuberculous infection of the eye. Some secondary vitreous haze.

large circumscribed masses of closely packed epithelioid cells surrounded by a very thin zone of lymphocytes. (This was reported by Dr. Muende.)

Before the results of the investigations were known she was given potassium iodide, 10 grains, t.d.s., without any helpful effect. She has made a marked improvement following the administration of arsenic trioxide, grain 1/50, one, t.d.s.—160 tablets in all.

Epidermolysis Bullosa.—GEOFFREY DUCKWORTH, M.R.C.P.

Miss J. B., aged 17. For the past eleven months has been troubled by the development of vesicles and bullæ on only slight traumatic provocation. The back of the hands is the part particularly affected, but she has some macular and papular lesions on the front of the legs. She also has acne vulgaris (with exaceriations) of the face and back and some of the papules readily form vesicles, and occasionally bullæ. There are many purplish patches of skin representing the sites of former lesions.

Her father and his brother have suffered from attacks of similar vesicles and bullæ following slight injury, but the attacks began only in manhood and do not last for more than about six months at a time.

Examination of the fluid from a typical bulla was negative for organisms, and cultures were sterile.

Treatment, which has included ascorbic acid and vitamin-P, and small doses of thyroid, has not had any demonstrable effect.

Dr. F. Parkes Weber: I think that Dr. Duckworth's case belongs to a variety of epidermolysis bullosa more or less completely localized to the hands or feet or both hands and feet, characterized by a recurrent bullous eruption in summer, the exciting cause being the hot weather more than local traumatism. The familial incidence is very striking, as first pointed out by E. A. Cockayne (*Brit. J. Derm.*, 1938, 50, 358), who, however, could find only one similar case recorded, namely, that in a boy aged 4 years, by F. Parkes Weber (*Proc. R. Soc. Med., Section Dermat.*, 1926, 19, 72). This boy is still troubled in exactly the same way in summer; the bullous eruption on his feet during summer makes standing painful and work in the R.A.F. became practically impossible. In this case I could obtain no family history of any similar condition. I have recently been told of another case in a boy, aged 6 years, whose father has always had the same tendency to get bullæ on the feet in summer. Rubbing is said to favour the development of the bullæ. There have been many reports in America on this "Cockayne" or "Weber-Cockayne" bullous eruption—see especially M. Waisman, "Recurrent Bullous Eruption of the Feet and Hands (Weber-Cockayne)—Localised Epidermolysis Bullosa", *J. Amer. med. Ass.*, 1944, 124, 1247, containing many references to the recent literature; see also J. B. S. Haldane, "A New Pedigree of Recurrent Bullous Eruption of the Feet", *J. Heredit.* (Baltimore), 1942, 33, 17.

I realize that the case shown by Dr. Duckworth to-day cannot as yet be classified as a typical example of the above variety of epidermolysis bullosa. Longer observation is required, together with exact details of the bullous eruption as it affected her relatives. It may have been more typical in these relatives.

Dr. Duckworth: I am much obliged to and thank Dr. Parkes Weber. This girl, however, developed her trouble last winter.

Dr. Parkes Weber: The case is certainly as yet altogether atypical, and the progress of the case as well as more exactness in the family history must decide the diagnosis.

Non-diabetic Necrobiosis Lipoidica.—G. B. DOWLING, M.D.

Woman aged 60. She says that the condition, which began in 1916, looked like a mosquito bite at first. From that time it has very gradually enlarged, extending by a solid thin cord-like edge, leaving in its wake a very special kind of delicate waxy scar through which veins are seen to course as clearly as in atrophoderma of the Pick-Hersheimer type. I first knew this patient twenty years ago, when the lesion looked just as it does now except that it now covers about three times the area that it did then, and part of the granulomatous edge has disappeared. A section made then showed that this growing edge had a tuberculoid structure. The case was exhibited with the diagnosis of ? sarcoid. Subsequently Dr. Goldsmith presented a similar case with the diagnosis of morphaea-like tuberculide; necrobiosis lipoidica had not yet been described. Dr. Wallace has presented two exactly similar cases

Dr. W. Freudenthal: Does Dr. Dowling think that the diabetic and the non-diabetic form might show clinical differences?

Dr. G. B. Dowling: I brought the case here really with the object of asking the question which Dr. Freudenthal has just put. I wondered whether these cases, with their extremely characteristic tuberculoid edge and waxy centre, might not be unrelated to the diabetic necrobiosis lipoidica.

Dr. W. N. Goldsmith: I cannot distinguish between diabetic and non-diabetic cases.

similar cases which he had been treating successfully with X-ray epilation, though some required a second epilation before final cure. I think they were mostly fairly early cases.

Multiple Chronic Ulcers of the Upper Trunk in a Young Woman. ? Acne Conglobata.—C. H. WHITTLE, M.D.

M. T., aged 22, a W.A.A.F. Three years' history of ulcers on the back and shoulders. Each ulcer takes two to three months to develop and heal. The first was on the shoulders. The latest was removed from left lower dorsal region for microscopy. Previous history good. Family history nothing relevant. There are now four fairly active lesions; one 1 in. diameter on left shoulder, bluish-red—mostly healed over but with a few pustules lying deeply on the edge. There are about 35 scars, oval or round, varying up to 5/8 in. diameter chiefly around the shoulder but also over the dorsal region, many showing a tendency to keloid.

There is a close similarity between the scars and smaller active lesions in my second case.

Wassermann and Kahn negative. Culture: *Staph. aureus*. Mantoux: 1:1000 Human ++; 1:1000 Bovine+.

Chest X-ray: No abnormality.

Biopsy: Shows ulceration and granulation tissue containing plasma cells, endothelial-type cells, and small round cells; polymorphs are present in places. The picture does not suggest nor does it exclude tubercle. [Section was shown.]

Multiple Chronic Ulcers of the Arms and Trunk. ? Cause.—C. H. WHITTLE, M.D.

D. H., aged 60. A ditcher. Twenty-five years' history of ulcers on the arms and upper trunk. Besides the large active but indolent ulcers on the upper arms there are very large numbers of oval or circular scars of healed ulcers on the back.

This case was shown earlier in the year (*Proc. R. Soc. Med.*, 1945, 38, 502). Since then penicillin intramuscularly has been tried without success, though a penicillin-sensitive *Staph. aureus* was obtained on several occasions from the lesions. No blastomyces have ever been seen or grown.

Recently, X-rays have been given a trial and he has had four doses of 200 r (Dr. Japha) to the lesion in the centre of the chest, which is now healing. He attributes the healing to the treatment.

Compare these lesions with those in my previous case of a young woman with three years' history of somewhat similar indolent ulcers.

COMMENT.—I am indebted to Dr. Duckworth for the suggestion that the ulcers might be due to anaerobic streptococci, and we have obtained some anaerobic streptococci in the last day or two from the man's unbroken pustules.¹ Whether that is going to be an important factor or not I do not know. The suggestion of tubercle has been put forward, but I have not found any evidence. A third suggestion has been artefact. One must not rule out artefact, I suppose, in long-standing cases of this sort, but to my mind, considering the temperament of both these patients, it is unlikely. The girl is intelligent and attractive, and I should have thought she was able to impress her personality in other more agreeable ways. The position of the lesions is also against that supposition. The man has had ulcers since he was 35; he is now 60, and he did not consult anyone about it until the last month or two, when he saw a doctor. They did not interfere with his work. I think the circumstances are against the idea that these lesions were designed to attract sympathy to himself.

The President: I have had one case where zinc peroxide had a certain effect, but a much better effect was obtained with a 2½% Milton. These cases in my experience have a very long history, and even when healed up, they relapse again some months later.

Circinate Sarcoids of the Face and Limbs.—GEOFFREY DUCKWORTH, M.R.C.P.

Mrs. M. C., aged 37, a cook. Nineteen months ago developed a bluish-red eruption chiefly on the arms and forearms, and legs, with isolated lesions on the sides of the face. When seen in June 1945 the lesions consisted of dusky rings, which had diameters varying from a half to several inches. The borders were mostly serrated, and not obviously raised. The centres of the lesions consisted of normal skin, or very slight atrophy. The lesions looked sub-epidermal.

A W.R. and a Kahn test were negative. A histological section shows the presence of

¹ POSTSCRIPT. (14.9.45).—The streptococcus has been grown in pure primary culture, has micro-aerophilic characters and gives some of the reactions of a hæmolytic enterococcus. The examination by Dr. A. I. H. Tomlinson is not completed.

active lupus of the lobe of the left ear and adjacent skin, still mildly active and showing nodules. She had not had treatment of any kind for many years. I first saw her in July 1944 and gave her calciferol, 150,000 i.u. daily. By September 1944 the lesions were showing obvious response and the dose was reduced to 100,000 i.u. daily. The lupus continued to regress slowly and she was kept on this dose until August 1945, when it was further reduced to 50,000 i.u. daily, which she is still taking. The glabellar lesion is now quite flat and shows mainly residual staining. There is still slight activity in the lower portion of the lesion. The ear lesions have completely healed and no nodules can be found. Her serum calcium level on October 31, 1945, was 10.5 mg. per 100 c.c. She has never been upset by the drug.

CASE IV.—Arthur M., aged 41. Extensive sheet of lupus on upper and inner aspect of right thigh, slowly progressive. Whole area thickened and raised, dusky red and rather scaly, resembling widespread lichenification. Section showed typical tuberculous structure. No previous treatment of any kind.

January 2, 1945: Given calciferol, 150,000 i.u. daily. At the end of the month the lesion showed response, being flatter and paler.

February 12, 1945: Dose reduced to 100,000 i.u. daily. Continued on this until August 13, 1945, since when he has been taking only one dose daily of 50,000 i.u. Serum calcium level on June 25, 1945, was 10.6 mg. per 100 c.c. By October 29, 1945, the whole lesion was flat, with residual pigmentation and islands of pink, clear, slightly atrophic skin. Serum calcium on that date: 10.1 mg. per 100 c.c. No intolerance to drug.

CASE V.—Mrs. Elizabeth G., aged 65. First seen December 12, 1943, with superficially ulcerative lupus of bulbous portion of nose and nasal vestibules of eight years' duration. She was treated until April 1944 with applications of liquid acid nitrate of mercury and radiostoleum by mouth with some response. Was then given calciferol, 100,000 i.u. daily until December 1944, when she ceased attending of her own accord because her nose had improved so much that it did not worry her any more. No intolerance to drug.

July 1945: No clinical lupus.

October 1945: Well. Serum calcium 11.2 mg. per 100 c.c.

CASE VI.—George Y., aged 45. Lupus involving whole of left ear and adjacent skin, twenty years' duration. More recent patch left malar area. All lesions active, with ulceration and crusting along helix.

First seen May 4, 1945. Confirmatory biopsy (left side neck). Calciferol given, 100,000 i.u. daily and continued ever since.

July 9, 1945: Good response. No further crusting and ear thinner and softer. Biopsy (apex of pinna, to exclude epithelioma because of thickening): Tuberculous histology.

Serum calcium, August 14, 1945 (after 100,000 i.u. calciferol daily approx. three months): 10.8 mg. per 100 c.c.

October 29, 1945: All lesions practically healed except for apex of pinna which is still crusting and slightly infected. No intolerance to drug at any time.

Of the other thirty-two cases, demonstrable improvement of varying degree has occurred in twenty-one cases, viz. of the total number of thirty-eight cases in which calciferol has been tried, there has been a favourable response in twenty-seven (approximately 71%). As regards the remaining eleven cases, in some calciferol has produced little appreciable change; in others, its effect has been difficult to assess, either because the lupus has more or less burned itself out or has become masked by previous scar-producing treatment of one kind or another, or by chronic radiodermatitis. Amongst the first-mentioned was the case of a child, a girl aged 10, who had a single small plaque of lupus in the right cheek of about one year's duration. We gave her calciferol, 50,000 i.u. daily for two months, at the end of which the lesion appeared a little flatter and paler. However, in view of the poor state of her general health we decided she needed full institutional treatment and arranged for her admission to the Treloar Home at

[November 15, 1945]

Lupus Vulgaris Treated with Calciferol

By G. B. DOWLING, M.D., and E. W. PROSSER THOMAS, M.D.

Dr. Prosser Thomas: We are presenting these cases of lupus vulgaris because of their good response to the oral administration of calciferol as virtually the only form of treatment. We have been treating lupus with calciferol since 1943. Including the six cases shown here to-day, we now have records of thirty-eight lupus patients who are being treated exclusively with calciferol or being followed up after stopping it.

It was Dr. Dowling who began giving calciferol in lupus, and the first patient to be treated with it is among those demonstrated to-day. [Case I.]

CASE I.—Sidney B., aged 30. This man was attending St. Thomas's Hospital with confluent lupus of the face. He had been receiving intensive treatment elsewhere for the previous five years, including daily carbon arc baths and applications of Finsen light two or three times a week. He had also had injections of Alepol and of N.A.B. His lupus, however, which had begun near the right ear when he was 20, had steadily extended and for the past nine months his whole face had been in a congested and œdematous state and showed no signs of subsiding. In August 1943, Dr. Dowling began giving him calciferol, 50,000 i.u. three times a day in tablet form. After taking these for a few days he said that he developed nausea and felt generally ill and had to go to bed. His face got worse, the congestion increasing and exudation began. He discontinued the calciferol and stayed in bed for a fortnight. By then the congestion had subsided and he noticed that his lupus had improved, so much so that he began taking the calciferol again of his own accord. In a month or so, however, he had a second flare-up in the face, associated with general malaise, though less severe. He again discontinued the calciferol temporarily. He has tolerated the drug well ever since, except for occasional slight "stomach disorder". His lupus continued to regress and after a few months the dose of calciferol was reduced to 50,000 i.u. twice daily. By July 1945 there were only two rather doubtful lupus nodules to be found; his skin otherwise was comparatively clear and showed only soft and very superficial scarring. The calciferol was then reduced to one dose of 50,000 i.u. a day, on which he continued until October 30, 1945, when he was taken off it altogether. His serum calcium on that date was 14.8 mg. per 100 c.c. Apart from the two questionable nodules in the right cheek, which have remained unchanged for some months, his lupus appears to have cleared completely.

CASE II.—Miss Jane P., aged 71, another of the cases presented to-day, was of a very similar congested type. She had had lupus for about five years. Her whole face, like that of Dr. Dowling's patient, had become distressingly angry and swollen and there was superficial ulceration of the cheeks, nose, and upper lip. The nasal mucosa was also involved, and the septum perforated. I first saw her in November 1944 and put her on calciferol, 150,000 i.u. daily, together with zinc cream and soluble sulphacetamide 5% to use as nasal plugs so as to try and clear up the secondary infection in the nose, which was practically blocked up with crusts. Her skin showed rapid response and by March 1945 was virtually clear, as it is to-day. She discontinued calciferol at that time and has shown no signs of relapse. The drug has never upset her.

CASE III.—Miss Emma C., aged 72. In contrast to the above two acute forms of lupus, this patient had a large plaque of lupus tumidus in the glabellar area, which had been present without appreciable change for about thirty years. She also had superficially ulcer-

active lupus of the lobe of the left ear and adjacent skin, still mildly active and showing nodules. She had not had treatment of any kind for many years. I first saw her in July 1944 and gave her calciferol, 150,000 i.u. daily. By September 1944 the lesions were showing obvious response and the dose was reduced to 100,000 i.u. daily. The lupus continued to regress slowly and she was kept on this dose until August 1945, when it was further reduced to 50,000 i.u. daily, which she is still taking. The glabellar lesion is now quite flat and shows mainly residual staining. There is still slight activity in the lower portion of the lesion. The ear lesions have completely healed and no nodules can be found. Her serum calcium level on October 31, 1945, was 10.5 mg. per 100 c.c. She has never been upset by the drug.

CASE IV.—Arthur M., aged 41. Extensive sheet of lupus on upper and inner aspect of right thigh, slowly progressive. Whole area thickened and raised, dusky red and rather scaly, resembling widespread lichenification. Section showed typical tuberculous structure. No previous treatment of any kind.

January 2, 1945: Given calciferol, 150,000 i.u. daily. At the end of the month the lesion showed response, being flatter and paler.

February 12, 1945: Dose reduced to 100,000 i.u. daily. Continued on this until August 13, 1945, since when he has been taking only one dose daily of 50,000 i.u. Serum calcium level on June 25, 1945, was 10.6 mg. per 100 c.c. By October 29, 1945, the whole lesion was flat, with residual pigmentation and islands of pink, clear, slightly atrophic skin. Serum calcium on that date: 10.1 mg. per 100 c.c. No intolerance to drug.

CASE V.—Mrs. Elizabeth G., aged 65. First seen December 12, 1943, with superficially ulcerative lupus of bulbous portion of nose and nasal vestibules of eight years' duration. She was treated until April 1944 with applications of liquid acid nitrate of mercury and radiostoleum by mouth with some response. Was then given calciferol, 100,000 i.u. daily until December 1944, when she ceased attending of her own accord because her nose had improved so much that it did not worry her any more. No intolerance to drug.

July 1945: No clinical lupus.

October 1945: Well. Serum calcium 11.2 mg. per 100 c.c.

CASE VI.—George Y., aged 45. Lupus involving whole of left ear and adjacent skin, twenty years' duration. More recent patch left malar area. All lesions active, with ulceration and crusting along helix.

First seen May 4, 1945. Confirmatory biopsy (left side neck). Calciferol given, 100,000 i.u. daily and continued ever since.

July 9, 1945: Good response. No further crusting and ear thinner and softer. Biopsy (apex of pinna, to exclude epithelioma because of thickening): Tuberculous histology.

Serum calcium, August 14, 1945 (after 100,000 i.u. calciferol daily approx. three months): 10.8 mg. per 100 c.c.

October 29, 1945: All lesions practically healed except for apex of pinna which is still crusting and slightly infected. No intolerance to drug at any time.

Of the other thirty-two cases, demonstrable improvement of varying degree has occurred in twenty-one cases, viz. of the total number of thirty-eight cases in which calciferol has been tried, there has been a favourable response in twenty-seven (approximately 71%). As regards the remaining eleven cases, in some calciferol has produced little appreciable change; in others, its effect has been difficult to assess, either because the lupus has more or less burned itself out or has become masked by previous scar-producing treatment of one kind or another, or by chronic radiodermatitis. Amongst the first-mentioned was the case of a child, a girl aged 10, who had a single small plaque of lupus in the right cheek of about one year's duration. We gave her calciferol, 50,000 i.u. daily for two months, at the end of which the lesion appeared a little flatter and paler. However, in view of the poor state of her general health we decided she needed full institutional treatment and arranged for her admission to the Treloar Home at

Alton. This was the only case in which we have had an opportunity of trying calciferol in lupus in childhood and in an early stage.

COMMENT

Calciferol (vitamin D₂) is a potentially toxic drug. It is a purely artificial substance, prepared by exposing the vegetable sterol, *ergosterol*, to ultraviolet light. It is said to be almost always contaminated with other possibly toxic by-products of irradiation, and to be more toxic than the naturally occurring vitamin D₃, which is found in animal products such as egg-yolk, butter, and fish liver oils, and is derived from irradiated animal sterols (Bicknell and Prescott, 1942).

Though apparently never tried hitherto in lupus, calciferol has been used in a variety of other diseases, often in very high dosage, and toxic symptoms have been observed not infrequently and reported in the literature. General well-being and a good appetite are said to be often the first symptom of poisoning. Anorexia may follow, together with nausea, vomiting, diarrhoea, and polyuria. Mental depression and headache may be early symptoms. Excessive doses mobilize phosphorus and calcium, thus broadly having an opposite effect to normal doses and producing metastatic calcification of soft tissues; of these, the renal tubules and arterioles and the media of the large blood-vessels are most affected. If the toxic doses are stopped the calcareous deposits are said almost to disappear. The serum calcium and phosphorus tend to be grossly raised, but not always—so that the serum calcium level is not a reliable guide. Serum calcium estimations in 12 of our cases after varying dosage and periods on the drug showed levels of between 10.1 and 10.8 mg. per 100 c.c. in 6 cases; in 3 cases the levels were approximately 11 mg., and in 3 cases there was hypercalcaemia, viz. 12.6, 13.8, and 14.8 mg. per 100 c.c. respectively.

From a review of the clinical results of many workers who have used calciferol in diseases such as chronic arthritis, Bicknell and Prescott (1942) found that most patients tolerated calciferol in doses of from 200,000 to 400,000 i.u. daily. They quote Steck and collaborators as stating, from extensive observations on over seven hundred patients, that few show toxic symptoms unless the dose exceeds 10,000 i.u. daily per pound of body-weight. Bicknell and Prescott, however, think these doses are far too high. From the clinical point of view they conclude (1) that, if large doses must be given it is useless to rely entirely upon blood calcium estimations as a safeguard, the clinical symptoms of poisoning being a better guide; (2) that the giving of highly concentrated vitamin D and calcium preparations together is unwise; (3) that fish liver oils should be the source of high doses of vitamin D; (4) that in patients with nephritis or cardiovascular disease large doses are unwise.

Regarding our patients, there have been symptoms of intolerance in eight of the thirty-eight. However, apart from Dr. Dowling's first case, who said he was severely upset on two occasions, the symptoms have been mild, consisting chiefly of nausea, loss of appetite, depression, or feeling out of sorts. We attributed the nausea mostly to simple irritation of the drug on the gastric mucosa, as it generally was felt soon after ingestion and then passed off. The symptoms have occurred usually in patients taking 150,000 i.u. daily, but the toxic threshold is said to vary considerably.

Dr. J. E. M. Wigley: I think we are all agreed that the results of this treatment, demonstrated by these six cases, is most striking; one might almost say epoch-making. The lady (Case 11) I saw at Charing Cross Hospital about two years ago when she had a definitely florid type of lupus vulgaris affecting her face. As she lives at Luton, and travelling conditions were very difficult at that time, and she was 70 years of age, I told her that I did not think any more could be done than was being done then. To-day I see her, to all intents and purposes, cured!

I think not the least important aspect of this treatment is an economic one. Treatment of lupus by other methods, e.g. Finsen light, general U.V.L., &c., has always had the great disadvantage of being very costly, both in apparatus and staff required, and in the patient's time, including loss of earning capacity. I do not wish to say that we can now dispense with these methods of treatment, but if the response to calciferol shows the continued, generally excellent results demonstrated to-day, a great advance will have been made in the method of dealing with this very serious social menace.

Dr. P. J. Feeny: I saw Case I several times when he was having Finsen light, and have not seen him again until now, when he is greatly improved.

Dr. R. M. B. MacKenna: There is some evidence that dermatologists in France are working along the same or similar lines and therefore I would urge Dr. Dowling and Dr. Prosser Thomas to publish an account of their work at an early date. I should like warmly to congratulate the exhibitors of these cases on the excellent results which they have achieved.

The President: We all congratulate Dr. Dowling and Dr. Prosser Thomas very sincerely. These cases are absolutely dramatic. I have not seen anything so promising for very many years.

Dr. G. B. Dowling: I have little to add except to thank Dr. Prosser Thomas for all the trouble he has taken in collecting and keeping records of these cases. Those that have been shown to-day have had no treatment whilst under our care except calciferol by mouth, but they are selected cases. As regards the other cases which we have treated with calciferol I think it is fair to say that all of them appear to have improved, but by no means all to the same extent.

Lupus Vulgaris Verrucosus of the Buttocks.—H. CORSI, F.R.C.S.

G. P., male aged 49.

Examination.—On the medial part of the buttocks are symmetrical areas, of a dark red, vegetative state of the skin, each area being rather larger than the size of a hand and fingers. The lesions are abruptly margined, the margins appearing much more active than most of the central area, where some places show spontaneous recovery.

There is a clear area between the medial margin of each lesion and the anal skin. Rectal examination was negative.

There is a patch of lichenification on the left shin, which has been present for twenty years. This has given no trouble except some itching, which, following some X-ray treatment, has now ceased completely.

The Wassermann reaction is negative.

History—statement by patient.—He was never conscious of anything abnormal until the early part of 1945. From 1941 to June 1944 he used to go to business in his car, but after that he took to riding a bicycle. Some six months later, he noticed blood on his underclothing, and found some blood blisters on the inner surface of his buttocks. Excepting for some soreness, the condition gave him no trouble, and was only seen by his general practitioner, Dr. Hector of Letchworth, in June 1945, when the patient was examined on account of lumbago.

He was in the Army in 1939-41, and went to France. He had a fall from a wagon early in 1940, suffering severe bruising of the buttocks. This took several weeks to clear, but the patient says that after some months there was nothing left to see of this bruising. He has always been in good health except for "bronchitis", which troubles him most winters. His mother and brother died of tuberculosis. An X-ray photograph of his chest shows a large cavity in the left upper zone.

Examination of the small quantity of sputum which he was able to produce shows the presence of tubercle bacilli. The E.S.R. rate is 12 mm.

Diagnosis.—Chronic phthisis, probably of many years' standing.

Treatment.—There was improvement following the use of penicillin cream, which was tried in the belief that the condition might be a staphylococcal vegetative condition. There was improvement, also, in two smaller areas treated with X-rays.

Section.—The appearances are typical of lupus vulgaris.

Now that I have seen Dr. Dowling's and Dr. Prosser Thomas's cases I shall certainly put him on calciferol, and I hope I may have an opportunity of bringing him up here again, when we may note the therapeutic result.

Dr. J. E. M. Wigley: Does anyone know of the use of calciferol in tuberculosis in other parts of the body?

Dr. Prosser Thomas: I have not seen any references to its use in concentrated form in tuberculosis elsewhere.

Alton. This was the only case in which we have had an opportunity of trying calciferol in lupus in childhood and in an early stage.

COMMENT

Calciferol (vitamin D₂) is a potentially toxic drug. It is a purely artificial substance, prepared by exposing the vegetable sterol, *ergosterol*, to ultraviolet light. It is said to be almost always contaminated with other possibly toxic by-products of irradiation, and to be more toxic than the naturally occurring vitamin D₃, which is found in animal products such as egg-yolk, butter, and fish liver oils, and is derived from irradiated animal sterols (Bicknell and Prescott, 1942).

Though apparently never tried hitherto in lupus, calciferol has been used in a variety of other diseases, often in very high dosage, and toxic symptoms have been observed not infrequently and reported in the literature. General well-being and a good appetite are said to be often the first symptom of poisoning. Anorexia may follow, together with nausea, vomiting, diarrhoea, and polyuria. Dr. J. E. M. Wigley: I think we are all agreed that the results of this treatment, demonstrated by these six cases, is most striking; one might almost say epoch-making. The lady (Case II) I saw at Charing Cross Hospital about two years ago when she had a definitely florid type of lupus vulgaris affecting her face. As she lives at Luton, and travelling conditions were very difficult at that time, and she was 70 years of age, I told her that I did not think any more could be done than was being done then. To-day I see her, to all intents and purposes, cured!

I think not the least important aspect of this treatment is an economic one. Treatment of lupus by other methods, e.g. Finsen light, general U.V.L., &c., has always had the great disadvantage of being very costly, both in apparatus and staff required, and in the patient's time, including loss of earning capacity. I do not wish to say that we can now dispense with these methods of treatment, but if the response to calciferol shows the continued, generally excellent results demonstrated to-day, a great advance will have been made in the method of dealing with this very serious social menace.

Dermatomyositis.—P. J. FEENY, M.B.

Mrs. A. B., aged 34. *History*.—Admitted seven months ago complaining of increasing weakness in the limbs, backache and for the previous two months a uniform pin-point erythema on the face. For the first month after admission she had a mild pyrexia with increasing wasting of the muscles. Her hair then fell out and the rash spread to the whole body. A dark pigmentation developed on the backs of the hands. The consistency of the muscles became progressively wooden and a pitting œdema developed on the limbs, pressure areas and face.

For the first four months she was treated with vitamins and massage twice a week without improvement; then glycine 5 one t.d.s. and thyroid grain one t.d.s. were substituted for the vitamins. Radiant heat and exercises twice daily were commenced ten weeks ago. From being unable to sit up, to raise her head, arms or legs or to feed herself, she could now sit out of bed, raise her head, raise her arms to shoulder level, raise her feet while in bed to a height of two feet, use a knife and fork and knit and write. The erythema has been fading uniformly for the past month.

Note.—There has been no induration of the skin at any time.

Investigations.—Electrical reactions: (a) Five months ago, all muscles tested responded weakly to strong faradism. (b) Two months ago, in addition there was a strong reaction to faradism in the left forearm, but not in the left leg, and a + + reaction to galvanism in the left leg.

Urine on admission: Albumin and acetone +, culture sterile.

Blood: Meinicke negative. Counts (four examinations), nothing abnormal. B.S.R., 26 Westergren units after one hour; 39 after one and a half hours; 50 after two hours.

X-ray: Shoulder and elbow joints—no evidence of bony changes.

Psychiatric: Suppressed fears with resulting exhaustion. Ego inflation.

Neurological (Dr. Rowland Hill): A polyneuritis plus myositis, probably due to a virus infection. I have recently seen two cases in sisters which developed simultaneously.

Biosis of skin: Sections were shown.

Dr. F. Parkes Weber: I suppose Dr. Feeny does not mean to say that there is hardly any skin factor in the present case of dermatomyositis. Cases of dermatomyositis mostly show œdema at various parts, especially about the eyes, and œdema is doubtless sometimes localized over the affected muscles. In this case, I understand, the patient had decided œdema, as is typical. I think such œdema is really of an active inflammatory nature. I think I am right in saying that as a rule not only is œdema found about the eyes, but that the skin at that part is often reddened and may even be scaly.

Dr. P. J. Feeny: What I had in mind was that the changes developed first in the muscles and not in the skin. There was so much œdema that we could not get into a vein.

Pityriasis Lichenoides with Necrotic Lesions (Habermann).—K. TATZ, M.D. (for L. FORMAN, M.D.).

Male, aged 31. Two attacks of dry pleurisy in 1930 and 1936. His sister had pulmonary tuberculosis. His own affection has been present for two years with new lesions appearing continuously. The condition was diagnosed in the Army as papulonecrotic tuberculide. Blood Wassermann and Kahn are negative, and Mantoux one in 1,000 is slightly positive. X-rays of chest show some thickening of diaphragmatic pleurae. Lesions occur mainly on limbs, buttocks, and upper part of trunk. The penis is affected, and there are two necrotic papules on the left palm. The lesions are as follows: (1) Small macules of waxy appearance on which a fine scale can be seen or produced by scraping; (2) small pinkish-brown papules; (3) larger hæmorrhagic papules, many covered by dark necrotic crusts which separate off to leave superficial ulcers terminating in varioliform scars. Each individual lesion takes about three weeks to develop into a superficial ulcer. The patient complains of slight itching. Treatment for the past six weeks has been weekly injections of 0.05 grammes of myocrisin; the number of new lesions appearing has definitely decreased for the first time in two years.

Points of interest: Involvement of palms, which is unusual; hopeful response to gold therapy; possibility of a tuberculous factor in the ætiology.

Section of a dull-red papule showed in the cutis a dense lymphocytic infiltrate mantling the vessels, some of which are showing multiplication of the cells of the media.

Lupus Vulgaris with Miliary Lymphatic Spread. Epithelioma.—R. P. STRANG, M.R.C.S., L.R.C.P. (for Dr. L. FORMAN).

Male, aged 53, first seen in August 1945. He first noticed a lesion on the back of the neck twenty-six years ago, which has been slowly increasing in size. At no time has he received treatment. Two years ago he noticed a growth on his neck in the centre of the original lesion. Physical examination revealed that the back and left side of the neck was the site of a brownish-red plaque, with atrophic scarring and serpiginous active border. Spreading peripherally over adjoining shoulder was an eruption of satellite papular lesions, lichenoid in character. In the centre of the original lesion was an epithelioma. On the vertex, at site of an old injury, was another area of scarred lupus vulgaris. Red blood count: 5.12 millions; hæmoglobin 100%; white cell count 5,800; sedimentation rate 6 mm. per hour. X-rays of chest normal. Blood Kahn negative. The epithelioma was excised and sections confirmed the diagnosis.

The case is shown because of the epithelioma arising on a plaque of lupus vulgaris that had had no previous treatment with X-rays or light, and because of the peripheral lymphatic spread of satellite lesions.

Dr. A. C. Roxburgh: I do not think it is very rare for an old lupus vulgaris to develop an epithelioma even if it has not had X-ray or light treatment. I remember a Continental paper (G. Truffi, *Arch. ital. Derm.*, 1933, 9, 443) in which it was found that most cases of carcinoma arising on lupus vulgaris occurred in patients who had had neither X-rays nor any other form of therapy. (1935, *Abst. Year Book Derm. Syph.*, Chicago, p. 301.)

Dr. G. B. Dowling: The impression most people have is that the incidence is higher in cases that have been irradiated. Quite a number of years ago it appeared to be agreed among dermatologists that for this reason lupus should not be treated by means of X-rays.

Abnormal Mesodermal Pigmentation.—ALICE CARLETON, M.D.

This is a healthy British girl of 13 with profuse bluish spots on the upper trunk and face, mouth, iris, and sclera. The condition is associated with bossy thickening of the skull, due to ballooning of the bones of the posterior cranial fossa. The spots differ from a blue nevus in their distribution—they are profusely disseminated—and in their histology, which shows no circumscription. They also differ from Mongolian blue spots, which have never been described in fair or red-haired children, and which tend to fade away instead of increasing in number. There is, further, nothing to suggest the presence of the diffuse mesodermal pigmentation associated with melanin excretion in the urine which has been described in animals. One must therefore conclude that this case represents an abnormality in mesodermal pigmentation which has not hitherto been described and which, at any rate in this instance, is associated with a skeletal abnormality, presumably congenital.

Dr. F. Parkes Weber: I suggest that the case may be an atypical pigmentary incomplete form of Recklinghausen's neurofibromatosis, to some extent analogous to that of a girl, aged 14 years, which I described in 1905 (*Brit. J. Derm.*, 1905, 17, 226, and 1909, 21, 49). The disease at that time was practically limited to a good deal of pigmentation of various types, but when examined again in 1926 (*Proc. R. Soc. Med.*, Sect. Derm., 1927, 30, 22) it had become a fully developed one of Recklinghausen's disease. She had been married for some years and had a child; the sprouting of the molluscous fibromata may well have been favoured in some way by the pregnancy and child-birth. What will happen in Dr. Carleton's patient when she grows up? The two cases are, however, not quite alike, and perhaps it would be better not to suggest that in Dr. Carleton's patient the condition is likely specially to be affected by marriage and possible pregnancy.

In a paper with Dr. J. R. Perdrau (*Quart. J. Med.*, 1930, 23, 151) I pointed out that as neurofibromatosis was a manifestation of an inborn abnormality of development, it was not surprising that it should be occasionally associated with other congenital or developmental abnormalities. In Dr. Carleton's patient there is the remarkable abnormality of the shape of the posterior part of the cranium. Moreover, she has definite over-extensibility of the elbow-joints, reminding one of what is seen in some cases of the Ehlers-Danlos syndrome. In this connexion it should be noted that the biopsy scars have a somewhat "atrophic" appearance, reminiscent of scars in patients with "cutis laxa" and the fully developed Ehlers-Danlos syndrome.

Reflections on the Development and Present General Application of Acrylic to Conservative Procedures

By ROBERT CUTLER, L.R.C.P.Lond., M.R.C.S., L.D.S.Eng.

THE purely practical exploitation of acrylic, inevitable in the stress and strain of the war years, has had its disadvantages, as this material lends itself so easily to every variety of expert manipulation, so that the essential principles underlying its character and usage have been somewhat neglected. As might have been imagined, the results of enthusiastic and quite empirical technical adventures have often been disastrous, and not made any the less serious by a spate of technical articles and notes advocating "short cuts" in procedure, this avalanche completely drowning the relative trickle of really scientific dental contributions in this specialized subject.

Methyl methacrylate first came into accepted dental use under the trade name "Paladon" in or about 1937, and it was about 1940 that a specialized product, under the trade name "Portex", first became available for purely conservative procedures, experience with which inspired an article by S. A. Leader (1942), so courageously titled "A Dental Revolution".

Very soon, however, in spite of the advantages of the new material, major difficulties arose, such as lack of colour fastness, inexplicable breakage, or detachment of restorations. This necessitated, for those whose faith was still unshaken, a further period of experimentation, review, and research, though, under the war conditions then obtaining, the latter was largely trial-and-error clinical investigation with bench testing under conditions of no real scientific accuracy.

It is interesting to note that lessons from these failures were being closely studied by other groups handling acrylic material, though it was not until 1943-44 that other proprietary brands became available, since when the user has the choice of at least three accredited sources of supply.

Bearing in mind the fact that for conservative procedures a dense homogeneous effect is essential, it can be realized that for this an extremely fine powder base is a prerequisite, and it is noteworthy that the sources of supply differ somewhat in their composition, to the extent that one is essentially of fine primary granule form, and at least one other of a primary coarse granule, secondarily ground into a fine powder base by mechanical means. Advantages are claimed for each, but so far no strictly controlled tests by any independent authority have yet been made available, and here at least is one opportunity for research by those qualified to undertake it.

In general, however, we can regard 1943-44 as the turning point in stabilization of supply, whereby new workers in the field have been spared many unnecessary difficulties, and fresh fields opened to those already possessing greater experience, the net result being that clinical work now undertaken bears, and most certainly merits, the strictest independent investigation.

In its purely general aspect, however, it does seem to me that one most important consideration has been consistently overlooked, and that is, how the paramount advantage of this material lies in the fact that it strictly conforms to the basic substitution principle which has been the foundation of dental technique for the last half century or more, and which separates the dentist's art from all other branches of mechanical precision work, which depend on the micrometer, the slide rule, or the blue print.

The dentist's method is to form the case in wax, to invest, and if necessary reverse it, to dissipate the wax, and to introduce into the cavity so formed his permanent material, whether vulcanite, acrylic, or molten metal, so producing a facsimile replica of his wax conception.

This process is virtually unique, and I cannot think of an exact analogy in any other sphere, and, indeed, we have only to compare the construction of a post crown in gold and china to one fabricated in acrylic, to see how closely the latter conforms to the time-tested principle. With the gold china preparation a post and metallic root-cap have to be prepared and fixed together, a china tooth, or facing purchased from the appropriate agency and subsequently ground to shape, being then joined to the base by cement or solder, so producing a composite result, mechanically sound enough, but only too often completely unæsthetic.

By the new method it is only necessary to fit a post to the canal of the prepared tooth, any non-corroding metal will serve, to build upon it a wax form to the character required,

Dr. R. M. B. MacKenna: It seems to me that these necrotic lesions, very widely scattered and extremely deep, are slower in healing than is usually the case in this particular disease. Also, on examining the patient I cannot see much sign of any lichenoid element. Originally a diagnosis of papulonecrotic tuberculide was made, and to my mind the clinical facts point more to that diagnosis than to the one now stated.

Dr. G. B. Dowling: I would certainly support the present diagnosis of pityriasis lichenoides acuta in this case; the angry-looking nodules with their striking, almost black hæmorrhagic central necrosis are most characteristic.

Dr. Louis Forman: I disagree with Dr. MacKenna although the differential diagnosis between pityriasis lichenoides with necrosis and papulonecrotic tuberculide may be difficult. The early papule did not show any suggestion of a tuberculous histology. Further the hæmorrhagic necrosis involved the whole of the larger papules and not the summit as in a papulonecrotic tuberculide. Flat, lichenoid papules were demonstrated.

Keratoderma Punctata.—CLARA M. WARREN, M.D.

Man of 57; shows typical lesions of keratoderma punctata on palms, fingers and soles. They have been present for only five years, and have slowly increased in number. Crateriform pits with surrounding thickening are the characteristic lesions. The man has worked as a butler until three years ago, and can give no history of contact with arsenic. None of his relatives has had any similar condition. The thickened hard punctæ cause him no trouble except on the finger tips, where pain occurs on pressure.

Dr. Louis Forman: Keratoses of the palms in middle-aged people might well be due to their having taken arsenic some years previously. In Dr. Warren's case there was no history of medicine which might have contained arsenic having been taken for rheumatism, epilepsy or chorea, but there are other possibilities, e.g. arsenic in drinking water, or absorption by inhalation of arsenic liberated by the action of moulds in wall-paper.

Dr. G. B. Dowling: I disagree with Dr. Forman in this case. If the warty lesions were due to arsenic one would expect arsenical changes to be present elsewhere; moreover, this is a not very uncommon picture and very characteristic of one of the late developmental abnormalities.

Dr. A. C. Roxburgh: In such a case would not arsenic be found in the hair or the epidermis?

Dr. Clara M. Warren: Can any treatment be suggested for this case?

Dr. R. M. B. MacKenna: If arsenic has played any part in the ætiology it might be worth while trying BAL (OX 217), a British preparation, the formula for which is secret, but which has the endorsement of the Medical Research Council, and is used for arsenic intoxication.

Reflections on the Development and Present General Application of Acrylic to Conservative Procedures

By ROBERT CUTLER, L.R.C.P.Lond., M.R.C.S., L.D.S.Eng.

THE purely practical exploitation of acrylic, inevitable in the stress and strain of the war years, has had its disadvantages, as this material lends itself so easily to every variety of expert manipulation, so that the essential principles underlying its character and usage have been somewhat neglected. As might have been imagined, the results of enthusiastic and quite empirical technical adventures have often been disastrous, and not made any the less serious by a spate of technical articles and notes advocating "short cuts" in procedure, this avalanche completely drowning the relative trickle of really scientific dental contributions in this specialized subject.

Methyl methacrylate first came into accepted dental use under the trade name "Paladon" in or about 1937, and it was about 1940 that a specialized product, under the trade name "Portex", first became available for purely conservative procedures, experience with which inspired an article by S. A. Leader (1942), so courageously titled "A Dental Revolution".

Very soon, however, in spite of the advantages of the new material, major difficulties arose, such as lack of colour fastness, inexplicable breakage, or detachment of restorations. This necessitated, for those whose faith was still unshaken, a further period of experimentation, review, and research, though, under the war conditions then obtaining, the latter was largely trial-and-error clinical investigation with bench testing under conditions of no real scientific accuracy.

It is interesting to note that lessons from these failures were being closely studied by other groups handling acrylic material, though it was not until 1943-44 that other proprietary brands became available, since when the user has the choice of at least three accredited sources of supply.

Bearing in mind the fact that for conservative procedures a dense homogeneous effect is essential, it can be realized that for this an extremely fine powder base is a prerequisite, and it is noteworthy that the sources of supply differ somewhat in their composition, to the extent that one is essentially of fine primary granule form, and at least one other of a primary coarse granule, secondarily ground into a fine powder base by mechanical means. Advantages are claimed for each, but so far no strictly controlled tests by any independent authority have yet been made available, and here at least is one opportunity for research by those qualified to undertake it.

In general, however, we can regard 1943-44 as the turning point in stabilization of supply, whereby new workers in the field have been spared many unnecessary difficulties, and fresh fields opened to those already possessing greater experience, the net result being that clinical work now undertaken bears, and most certainly merits, the strictest independent investigation.

In its purely general aspect, however, it does seem to me that one most important consideration has been consistently overlooked, and that is, how the paramount advantage of this material lies in the fact that it strictly conforms to the basic substitution principle which has been the foundation of dental technique for the last half century or more, and which separates the dentist's art from all other branches of mechanical precision work, which depend on the micrometer, the slide rule, or the blue print.

The dentist's method is to form the case in wax, to invest, and if necessary reverse it, to dissipate the wax, and to introduce into the cavity so formed his permanent material, whether vulcanite, acrylic, or molten metal, so producing a facsimile replica of his wax conception.

This process is virtually unique, and I cannot think of an exact analogy in any other sphere, and, indeed, we have only to compare the construction of a post crown in gold and china to one fabricated in acrylic, to see how closely the latter conforms to the time-tested principle. With the gold china preparation a post and metallic root-cap have to be prepared and fixed together, a china tooth, or facing purchased from the appropriate agency and subsequently ground to shape, being then joined to the base by cement or solder, so producing a composite result, mechanically sound enough, but only too often completely unesthetic.

By the new method it is only necessary to fit a post to the canal of the prepared tooth, any non-corroding metal will serve, to build upon it a wax form to the character required,

to make a check test for the appropriate colour and distinctive markings, and thereupon, by the time-tested principle of substitution, produce a perfectly æsthetic restoration, adequate in strength, kind to the tissues and with true finesse of mechanical fit: no laborious soldering, fitting, or grinding or any of the tedious procedures which smack more of the fitter's bench than the vital art of the dental surgeon. This is perhaps an over-simplification and it is freely admitted that composite restorations of cast metal and acrylic have a high place in this specialized field, but it illustrates the point I have in mind with which any student of dental history would surely agree.

A further primary principle can be noted here, if one recalls that before the war soap carving of tooth forms was rightly favoured in some British schools, though inevitably it was regarded as an end in itself in the sense that it was meant to inculcate an appreciation of the æsthetics of form, and the value of manual dexterity generally: beyond that it was impossible to go, as the student could hardly be expected to visualize a transformation of his carving into a mass of gold, china and cement. With the acrylic medium available, however, he can now carve his forms with the added incentive of knowing the results of his labour can be reproduced in a tooth-like solid, losing not one whit of the character which he has so carefully formed. This point should not be neglected by the schools where facilities for experiment and research should be superior to those of the free-lance worker.

I have already referred to the spate of technical articles as being disadvantageous, and we do not lack for specific examples, for as early as 1942 I drew attention (Cutler, 1943) to the fact that test inlays of M.O.D. form, made by the pressure plunger and sprue channel method, were in no way superior, and usually inferior, to those made by the simple "split flask" technique, even when the pressure plunger assembly was made as a precision mechanical unit. At that time the reason was not fully clear to me, but what was abundantly clear was the fact that other workers had noticed the same phenomenon, and in some cases had gone to extravagant lengths in the field of mechanical improvisation in order to justify its continued use: thus one worker advocated an assembly whereby the inlay cavity part was boiled in water whilst an electric cooling fan was made to play on the pressure plunger and reservoir—and further, one manufacturer, not one whit discountenanced by these procedures, did in fact advocate the pressure plunger technique as a standard method.

In this connexion it is interesting to show the value of accurate scientific information, in that it was a fresh study of the classic articles by Tylman (1942*a, b*) that gave us the clue to this apparent anomaly. Tylman had made it very clear that the greatest acrylic mix fluidity range was fairly critical, lying between 70° and 90° C., that the greater part of the polymerization occurred in this period, and that any additional pressure after this point only resulted in additional strain in the processed piece. In such circumstances it would be reasonable to suppose that using the two-part flask method, with the mould filled to excess, there should be a point in the initial curing process, when, as the temperature rose progressively, fairly sudden closure should occur under a constant spring pressure, indicating the phase of maximum fluidity and high rate of contraction, but this had never been a marked feature in our experience.

In considering the whole matter again, however, we realized that in the two-part flask technique the extruded "flash" being subject to greater pressure and certainly greater initial heat, in virtue of its peripheral position, hardened first, thus obstructing closure at the critical period, and that the same premature hardening occurred in the reservoir cylinder of the pressure plunger method. In each case the effect, as far as "follow up" of contraction was concerned, was bad, but obviously would be worse, if not disastrous, in a reservoir and sprue channel system, and this was strictly in accordance with the observations made. To elucidate the matter further, and if possible to confirm Tylman's observations, we developed a closed flask assembly with an excess charge of material located in direct contact with the main mass under control of a pressure pin with screw thread feed, operated from the outside of the sealed and clamped flask assembly, and, as might have been expected, it was found that almost effortless turning of the threaded pressure pin could be effected during one phase of the initial curing period, resistance to turning pressure having been constant both before and after this phase.

In view of these findings certain modifications in the two-part flask processing technique were obviously called for and these were summarized in a further article (Cutler, 1944) and, to my knowledge, the validity of the technique as then formulated has not since been challenged. This whole incident has been quoted at some length in showing the value of accurate scientific information being freely available when difficulties are encountered, as distinct from the employment of mechanical ingenuity to compensate for errors arising from a misconception of the phenomena involved.

At this stage, it might be suggested that the greater wealth of articles of a scientific nature on prosthetic aspects of acrylic manipulation would be of material assistance,

and certainly articles similar to that contributed by Taylor (1941) come within this category, but even so there is some little danger of carrying the analogy too far, as the permissible margin of error in delicate conservative restorations is obviously infinitely less than in relatively massive prosthetic pieces. For example, at first blush the fracture of M.O.D. acrylic inlays, when exposed to negligible occlusal stress, might be considered analogous to the incidence of fracture across the vault of a partial acrylic denture which is not uncommon, but in actual fact, in the latter instance, it is the combination of low resistance to extension (low tensile strength) operating on one surface of the denture and high resistance to compression operating on the other surface that causes cracking and fracture, if by any mischance an over-great bending or squeezing force is applied across the long axis of the vault of the denture.

On the other hand in the acrylic denture of M.O.D. type uncontrolled—and often unnoticed—contraction of the piece, prior to cement fixation under positive pressure, may well produce internal strains of an altogether different character and quality, but none the less leading to spontaneous fracture under negligible load.

Again, because in prosthetic practice the virtually complete unbreakability of acrylic teeth is a known fact, it should not be assumed that every form of acrylic conservative restoration will be equally successful, and, indeed, in gold acrylic composite bridgework spans, very considerable trouble has been experienced, due largely to the present relatively low tensile and sheer strength of the material; a study of progress in composite bridge-work design being especially instructive. In the early days it was considered sufficient to place a plain round bar in the body of the span, later cranked to prevent torsional breakdown of the material, but in many cases a complete fracture of both metal bar and acrylic mass was noted. The next step was a progressive thickening of the reinforcing metal element, which, however, in the end defeated its own object, as the acrylic became a virtually unsupported veneer, the result being a crazing and cracking with eventual complete disintegration.

The problem has now been solved by diffusing a relatively delicate reinforcement throughout the acrylic mass, or by employing a cast metal occlusal surface to which the body of acrylic is fused, and it is interesting to note that our own trends of design find confirmation in a recent article by Salisbury (1945) which, although essentially practical, is one of the most sober and helpful reviews available recently. On the other hand examples can be cited of the value of articles on prosthetic matters, such as the demonstration of internal strain in large dentures made in clear acrylic, either by solvent crazing or by the polariscope, suggesting that similar phenomena may occur in delicate conservative pieces, particularly when one recalls how much greater the applied unit pressure can be, and how easy it is to apply such enhanced pressures at the wrong stage of the time-heat-pressure cycle.

To consider the matter from another angle, the evaluation of the suitability of acrylic by response to simple mechanical testing has sometimes led us astray, as, for instance, the initial acceptance of Brinell hardness as a criterion of wear resistance. (Examples B.H.T. acrylic 26-35, 24 ct. gold 29, 22 ct. gold 54, amalgam 80-100.) On this scale doubts were expressed as to the wear resistance of acrylic, but the fact seems to be the inherent resilience factor, and the presence of saliva as a lubricant confers a quite unexpectedly high resistance to abrasion. The plastics engineer would, however, be not so greatly surprised, as he would bear in mind the performance of laminated plastic bearings and gear wheels in standard industrial practice. For instance, it has been found that plastics employed for the master bearings in steel roller mills have a life four times as long as phosphor-bronze bearings, the coolant lubricant being water, thus having a most interesting analogy to the saliva performing the same function in the mouth: further, in gear drive practice when the load and drive were irregular the shock-resisting quality inherent in the plastic gear train invariably produced a more even and more smooth transmission. ("Plastes" 1943.)

Peyton and Mann in a masterly contribution (1942) seemed well aware of this phenomenon and considered the Bierbaum scratch test as a better indication of wear-resisting properties, and worked out a "scratch resistance number" for a series of materials which seem more in accord with clinical behaviour. (Examples S.R.T. acrylic 49-61, 24 ct. gold 44, 22 ct. gold 71, amalgam 150.) It would appear the resilience factor is of significance here, but this property, from our standpoint, is a rather two-edged sword, as, whilst the shock-resistant quality apparently aids its resistance to abrasion, it is equally clear that the consequent lack of rigidity would be, and is, a positive danger in thin section, or unsupported, acrylic restorations, so that with material at present available the incisal stress, and we can only assume that the support inherent in a good jacket crown preparation, in which no part of the restoration is exposed to leverage or flexural

to make a check test for the appropriate colour and distinctive markings, and thereupon, by the time-tested principle of substitution, produce a perfectly æsthetic restoration, adequate in strength, kind to the tissues and with true finesse of mechanical fit: no laborious soldering, fitting, or grinding or any of the tedious procedures which smack more of the fitter's bench than the vital art of the dental surgeon. This is perhaps an over-simplification and it is freely admitted that composite restorations of cast metal and acrylic have a high place in this specialized field, but it illustrates the point I have in mind with which any student of dental history would surely agree.

A further primary principle can be noted here, if one recalls that before the war soap carving of tooth forms was rightly favoured in some British schools, though inevitably it was regarded as an end in itself in the sense that it was meant to inculcate an appreciation of the æsthetics of form, and the value of manual dexterity generally: beyond that it was impossible, to go, as the student could hardly be expected to visualize a transformation of his carving into a mass of gold, china and cement. With the acrylic medium available, however, he can now carve his forms with the added incentive of knowing the results of his labour can be reproduced in a tooth-like solid, losing not one whit of the character which he has so carefully formed. This point should not be neglected by the schools where facilities for experiment and research should be superior to those of the free-lance worker.

I have already referred to the spate of technical articles as being disadvantageous, and we do not lack for specific examples, for as early as 1942 I drew attention (Cutler, 1943) to the fact that test inlays of M.O.D. form, made by the pressure plunger and sprue channel method, were in no way superior, and usually inferior, to those made by the simple "split flask" technique, even when the pressure plunger assembly was made as a precision mechanical unit. At that time the reason was not fully clear to me, but what was abundantly clear was the fact that other workers had noticed the same phenomenon, and in some cases had gone to extravagant lengths in the field of mechanical improvisation in order to justify its continued use: thus one worker advocated an assembly whereby the inlay cavity part was boiled in water whilst an electric cooling fan was made to play on the pressure plunger and reservoir—and further, one manufacturer, not one whit discountenanced by these procedures, did in fact advocate the pressure plunger technique as a standard method.

In this connexion it is interesting to show the value of accurate scientific information, in that it was a fresh study of the classic articles by Tylman (1942*a*, *b*) that gave us the clue to this apparent anomaly. Tylman had made it very clear that the greatest acrylic mix fluidity range was fairly critical, lying between 70° and 90° C., that the greater part of the polymerization occurred in this period, and that any additional pressure after this point only resulted in additional strain in the processed piece. In such circumstances it would be reasonable to suppose that using the two-part flask method, with the mould filled to excess, there should be a point in the initial curing process, when, as the temperature rose progressively, fairly sudden closure should occur under a constant spring pressure, indicating the phase of maximum fluidity and high rate of contraction, but this had never been a marked feature in our experience.

In considering the whole matter again, however, we realized that in the two-part flask technique the extruded "flash" being subject to greater pressure and certainly greater initial heat, in virtue of its peripheral position, hardened first, thus obstructing closure at the critical period, and that the same premature hardening occurred in the reservoir cylinder of the pressure plunger method. In each case the effect, as far as "follow up" of contraction was concerned, was bad, but obviously would be worse, if not disastrous, in a reservoir and sprue channel system, and this was strictly in accordance with the observations made. DISCUSSION ON SURGERY OF THE PATENT DUCTUS ARTERIOSUS

(INFECTED AND UNINFECTED)

Mr. John B. Hunter: For many years the branch of congenital heart disease associated with a patent ductus arteriosus has been the subject of much discussion. Many of these discussions have been academic and have been associated with explanations to account for the closure of the ductus, none of which is really satisfactory.

Barclay, Bancroft and others from the experimental side, using radiological methods in sheep fetuses, have demonstrated that blood ceases to flow through the ductus within a few minutes of birth; but this does not necessarily mean that the ductus is completely occluded as rapidly as would appear from the radiological findings. The ductus is a thick muscular tube at this time and it is possible that with the filling of the whole pulmonary system with the first breath, the flow of blood through the ductus ceases and that vessel, as is common with all vessels denuded of blood in their interior, immediately contracts, and after its occlusion, fibrosis takes place producing the ligamentum arteriosus. This may be over-simplification of the problem but it is one to which I will refer later in connexion with the persistent patent ductus and the flow of blood in it.

The problems associated with a patent ductus arteriosus have had fresh light thrown on them by the intervention of the surgeon in this field, and to some extent theoretical views have been replaced and in the course of time most of the problems will be solved.

Ligation of the patent ductus arteriosus was first suggested by Munroe in 1907 and the first attempt was made by Graybril and Strieder in 1938, but this was not successful. The first successful cases were reported by Gross in 1939 and his approach is now generally used with modifications in the technique. All authorities agree that the patent ductus carries a definite morbidity but it is extremely difficult to assess, and, further, it has not been possible to say accurately to what extent it shortens life, but that patients with a patent ductus do not attain old age is generally agreed, although Gilchrist has reported a case of spontaneous closure in a child.

The chief danger is infection causing a subacute endocarditis which is fatal, but it is to be remembered that these patients, apart from the infective danger, have to live the restricted life associated with a cardiac lesion. The diagnosis of the condition is not always an easy one, and this is not the place to enter into such a discussion, it being in the realm of the cardiologist. There are, however, some cardinal points in the uncomplicated case that may be mentioned. The patients usually are known to have had a cardiac lesion from childhood. They are usually small in size and they may complain of shortness of breath, but usually as they have had the lesion all their life, they are not conscious of this disability. On examination they have no finger clubbing and usually no cyanosis. Palpation over the pericardium may or may not reveal a turbulent heart action, and a thrill over the upper part of the left chest, its maximum about the second interspace. Auscultation reveals the characteristic murmur suggesting a heavy machine shop and known as the "machinery murmur"; its essential feature, originally described by Gibson, is its continuous quality.

An X-ray of the chest usually reveals certain characteristic features, the pulmonary artery is enlarged so that a bulge can be seen below the aortic knuckle and there is usually some enlargement of the heart. The vascular shadows in the lungs are very obvious and in some cases markedly so.

My experience has been chiefly with uninfected cases, only two out of fifteen cases suffered from bacterial endocarditis.

In consultation with Dr. East, who has seen all the cases with me, a decision has been made as to whether operation should be undertaken or not. We have decided that the mechanical defect, together with the risk to life, is sufficient to warrant surgical intervention, in the uncomplicated case, with the exception of the very young; the parents of these children being told to bring the child up at a later date with a view to operation. In the majority of cases a search for septic foci is made; usually, owing to the cardiac condition patients have not had their tonsils and adenoids removed and, where necessary, this is now a routine, the operation being performed under prophylactic doses of the sulpha drugs. Breathing exercises are instituted as soon as the patients come into hospital and are continued throughout their stay. The operative technique has been

stress, allows only the good qualities of the shock-resistant material to be made manifest.

Again, the question of change, both linear and volumetric, due to water imbibition, is clearly of significance, and though at first lack of cementation adhesion was attributed to this sole cause, clinical evidence indicates this assumption is not wholly true, though it is obvious that time be allowed for full water absorption by the processed piece prior to surface drying and cementation.

Tylman (1942a) assumed the original net processing shrinkage of 0.5% approx. was more than compensated by what he called the "available total water expansion" of 0.8 to 1.0%, thus leaving a plus final dimensional change, and this he repeated in a later communication (Tylman, 1942b), but Peyton and Mann (1942), as a result of tests on one-inch lengths of one-quarter-inch square section acrylic specimens, although confirming there was a linear shrinkage of 0.2 to 0.5%, becoming maximal after drying for a month in air at room temperature, said that the linear expansion after prolonged immersion in water was only of the order of 0.02%, thus leaving a total shrinkage discrepancy of 0.48% maximum, which, taken by itself, would suggest the need for a coating investment expanding within such limits. Peyton and Mann, however, did admit their figures had been challenged, and that linear measurements after processing could be invalidated by the tendency of the material to stick to the moulds, and further they admitted that correct closure technique with excess could, in practice, be made to compensate for the initial shrinkage discrepancy.

The salient clinical fact that remains, however, is that in all the jacket crowns made by the author since 1941 only one showed evidence of loosening as far as it was possible to check on regular patients, and, further, that all the jacket crowns that subsequently had to be remade (owing to the use of non-colour-fast material prior to October 1942) needed complete slitting to the root stump, and crosswise leverage in the slit to break them open before they could be removed, so that due precautions being observed, it seems unlikely that water sorption is of too great significance in connexion with cementation, adhesion. What does remain, however, is the undoubted fact of volume change in drying, and it is conceivable that an anterior crown or inlay in a mouth breather might well be susceptible to such changes with fatal results to the fixation of the restoration, and research on this point is obviously indicated. To summarize progress, therefore: (1) The use of colour-fast dyes and stable opacifiers of the native clear acrylic seems established, judging by experience with material available since 1942-43. (2) Improvement in preparation of the basic powders has facilitated the production of a dense homogeneous body mass which is so essential. (3) Knowledge of temperature control, and of the mischievous potentialities of the exothermic reaction, is more widespread, so that porosity, and, equally important, lack of density, in the processed piece, can be regarded as a wholly avoidable evil. (4) Knowledge of control of contraction has advanced to a point where the physical shortcomings of any given restoration can be estimated in advance, and steps taken to compensate for it. (5) The primary supposition of high wear resistance has been amply confirmed in study of clinical behaviour of specimens after three to five years. (6) Design and planning of reinforcement is becoming stabilized judged by the general consensus of opinion of experienced clinical workers.

As regards the direction in which we should look for improvement or help, the following suggest themselves: (1) Investigation of effect of "fillers" of a siliceous nature to increase hardness. (2) Further knowledge of the time-heat-pressure cycle in respect of control of contraction in any given case. (3) Investigation into the effects of monomer showing less shrinkage, and the use of co-polymers of methyl methacrylate itself. (4) Further study of water sorption changes. (5) Strict comparisons of existing materials in tensile impact and sheer strengths either in the pure form, or with specified reinforcement.

This paper is not to be regarded as a scientific study, but as a memorandum of observations based upon a practical empirical study of the material for five years. My own belief is that it has earned its place in our technical armamentarium, and that every scientific effort should be made to investigate all aspects of the use of the material.

Already the names of many workers in this field do not lack for distinction—Leader, Tylman, Peyton, Mann, Salisbury and others—whilst in the related field of acrylic prosthesis we think of Sweeney, Paffenbarger, Taylor, Osborne and so on, and it is to be hoped that the efforts of other distinguished workers will soon be directed to this subject.

sweeping past the opening acts like a Sprengel's pump. It might be claimed that an artery helps to maintain its lumen full by contracture and this is undoubtedly so, but at this point the aortic wall has a defect, the ductus opening, and, further, the wall is anchored, again by the ductus, so that contraction at this point is not so complete as it is elsewhere in the vessel.

Further evidence of this view is to be found in the remarkable change that takes place after tying the ductus in infected cases. Here shortly after ligation the number of colonies of organisms that can be grown from the peripheral stream is reduced in a most dramatic manner. This can be explained by the fact that the infected blood passing over the vegetations in the pulmonary artery passed before ligation directly into the arterial circulation but after ligation passes into the pulmonary capillary bed where the organisms are presumably destroyed. I have attempted to explain some of the problems presented to us, but both views may be right: it is possible that with the heart acting quietly and the patient at rest, the flow may be from the pulmonary artery to the aorta, then with activity and the heart more vigorously engaged, the pressure in the aorta rises, thus forcing the blood back through the ductus. Such an explanation would account for the slight enlargement of the heart, and the increase in the pulmonary vessel shadows.

On the surgical side, it has been reported from time to time that the murmur has returned after operation; this would suggest the ductus has opened again after being tied. Two experiences of my own can be given in this connexion. In the first the case was an adult with gross infection who eventually died, the murmur having returned about a week after operation. At post-mortem the ligatures were in situ but a thin probe could be passed along the ductus. In this case I think the ductus itself was full of vegetations and that when the ligatures were tied the lumen was occluded, but liquefaction of the vegetations took place, allowing a small channel to appear. The second case was a boy with a very short broad ductus. I tied my first ligature with apparent occlusion, but when I tied my second I found that the first was quite slack, I removed it and replaced it. If I had only put on one ligature I think the murmur might have returned.

Surgeons are not happy about ligation in continuity, and there is no doubt that the next forward step in this region is to divide the ductus completely. I so far have not had sufficient courage to do this, but it is now being done with increasing frequency by others. Crafoord in a personal communication tells me that he always divides the short ones, and ties the long ones, in the latter case injecting a sclerosing fluid between the ligatures. Gross has been wrapping cellophane round the ductus after ligation and this substance causes an intense local reaction.

The difficulties to be encountered during the operation are:— the problems in connexion with exposure, local bleeding of a slight character but sufficient to obscure the field and make the procedure tedious, puncture of the pericardial extension along the ductus with a small constant stream of pericardial fluid, the presence of glands in the arch of the aorta which are sometimes difficult to clear from the ductus, and the most serious, the tearing of the ductus either while it is being defined or due to the ligature material cutting through it. In one of my cases I think the ductus was torn, but fortunately after I had the ligatures round it and was able to secure it.

The complications after operation are on the thoracic side, that is, the patient may get a little fluid or air or both in the pleural cavity. In no case has there been cause for anxiety during convalescence, and by expanding the lung with positive pressure to reduce the air in the cavity there should be no dangers from this side. In an uncomplicated case there should be no blood in the pleural cavity.

The usual convalescence is quiet in children; they are well after twenty-four hours, and it is probably only conservatism that confines them to bed for a week or ten days. One case I must mention, as this is a blot on the series of uncomplicated cases. The child had her ductus ligatured and was getting up when on the tenth day she developed a temperature, a blood culture showed an infection with *Staphylococcus aureus*; there were no mediastinal or chest signs. Penicillin was not readily obtainable at that time and she was transferred to the experimental penicillin unit at the Middlesex Hospital. After a course of penicillin her temperature fell only to rise again in a few days and on this occasion the staphylococcus was found to be penicillin-resistant, and the patient eventually died. I think in this case the operation was undertaken too soon after the child's adenoids were removed, a period of twenty-one days.

I have only operated on two infected cases, both of whom died subsequently. I did not find the operation any more difficult because of the infection. In one case, however, the patient had convulsions during the operation and it is possible that these were due to multiple emboli displaced by manipulation; this was the same case in which the murmur returned after ligation.

the same in all cases and the approach used was that originally described by Gross, although the approach is a limited one, much more so than the chest surgeon usually employs, but it allows the reconstitution of the chest wall more completely and permits, in my opinion, the re-expansion of the lung more easily than the usual thoracotomy incision, although it does not allow the same access in dealing with complications of the operation if one is so unfortunate as to meet them. The patient is placed on his back on the operating table with a small sandbag under the left shoulder, the arm extended above the head; this allows a slightly lateral approach to the mediastinum. A curved incision is made downwards from the sternum opposite the second interspace to the axilla. This incision allows better healing than the straight one. The skin flap is turned up, the pectoralis major incised in the line of its fibres up towards the axilla, the pectoralis minor fibres being divided. The second costal cartilage is divided obliquely close to the sternum, the internal mammary artery is usually not interfered with, but if injured it is divided and ligatured. The pleural space is opened in the second interspace and a single rib spreader introduced, the lung collapses away from the field of operation after the pleura is opened and is lightly packed off with a gauze roll. It is uncommon to find adhesions between the lung and the mediastinal pleura, but if found they are gently separated.

The mediastinal pleura is divided about an inch below the phrenic nerve, which is a noticeable landmark. It is my practice then to clear the lower mediastinal surface of the pleura; this allows certain small veins to fall away into the lax tissue causing no further trouble, or, if they have to be dealt with, they are easily ligated. This blunt dissection also discloses the vagus nerve in the region where the recurrent nerve is coming off, and this latter nerve can be seen winding tightly round the aorta and running more from left to right than is usually realized. This landmark indicates the upper and posterior part of the ductus and by dissection down to the pulmonary artery the lower and left edge of the ductus is defined. The anterior and right edge are more difficult; at first sight there appears to be no space between the arch of the aorta and the pulmonary artery, but by gentle dissection a space is determined and the ductus defined. The posterior surface has now to be freed and it is here that the ductus may be torn; great care, therefore, has to be taken to separate it from the bronchus. The ductus itself when defined is very short and runs more antero-posteriorly than one expects. It can be elongated by gentle traction with a finger on the pulmonary artery while the ligatures are being passed. My custom is to use No. 8 silk and to tie two ligatures, and care should be taken not to damage the recurrent nerve with the ligatures.

The mediastinal pleura is then sutured and the lung expanded by positive pressure. The cut surfaces of the costal cartilage are approximated with a catgut suture, after which the intercostal space is closed. Care should be taken in the closure of the rest of the wound as it tends to heal with an unsightly scar, but since the use of the curved skin incision this is not noticeable. During that period of the operation before tying the ductus the operator is conscious of a thrill, in some cases it is so marked as to be transmitted to the dissecting instruments. This thrill is easily stopped by a finger on the ductus, and it is remarkable what slight pressure is necessary to obliterate the channel; it does not give the impression that one is dealing with arterial pressure. The wall of the ductus itself varies very considerably in thickness. In the majority of cases it is very thin, and in two instances I have been able to see blood moving in the vessel. In both these cases I have had the impression that the flow was from the pulmonary artery to the aorta. This is against all the views previously expressed, but those views have been largely theoretical. It has always been assumed that the flow was from the aorta to the pulmonary artery on the grounds that the pressure in the aorta was more than in the pulmonary artery and also that the enlargement of the heart suggested an extra load in the pulmonary side, this is further strengthened by the increased pulmonary vessel shadows as seen by X-rays. It has been estimated that the flow through the ductus is very large, up to 50% or more of the left ventricular output. It is remarkable that this extra work does not result in more serious signs of myocardial insufficiency, and when the increase in blood-pressure and the great increase in size of the heart that occurs with an arteriovenous fistula of similar size caused by injury is considered, one must ask if there is not some factor present in the congenital case that has not yet been explained.

I believe that the greater part of the flow is from the pulmonary artery to the aorta. It is a little difficult to understand why when the *fœtal* circulation ceases the blood-stream should suddenly reverse, and I think the chief factor is to be looked for in the position of the ductus in relation to the aorta; the opening is placed at the extreme point of the concavity and the high pressure current of blood in the aorta sweeps to the convexity, thus leaving an eddy at the opening of the ductus; further, the blood

Crafoord *et al.* (1944) stated that the absence of the diastolic fraction was incompatible with the diagnosis. It therefore seemed certain that no diastolic murmur meant no patency of the ductus. The accuracy with which the diagnosis could be made was shown by the fact that Shapiro and Keys (1943) found that only two errors had been made in 140 recorded cases submitted to operation. The only certain method of establishing the presence of complicating infection was by blood culture which should be done by the "shake method", but Gilchrist (1945) had pointed out that chest radiography might be of value in demonstrating pulmonary infarcts which only occur in the presence of infection.

The only certain method of establishing the presence of complicating infection was by blood culture which should be done by the "shake method," but Gilchrist (1945) had pointed out that chest radiography might be of value in demonstrating pulmonary infarcts which only occur in the presence of infection.

The indications for surgical closure of the ductus required careful consideration. Infection was undoubtedly an absolute and urgent indication for operation as the prognosis in unoperated infected cases had been almost universally fatal in the past, whereas about 60% (in his own series 7 out of 12) were cured of their infection by closure of the ductus. The severity of the infective process varied from case to case but all patients went progressively downhill so that, when infection had occurred, it was important that its presence should be recognized early and operation undertaken before the patient's general condition had deteriorated. The dogmatism with which one could recommend surgical treatment for cases suffering from superimposed infection had perhaps been slightly diminished by the introduction of penicillin in the treatment of other forms of penicillin-sensitive bacterial endocarditis, for a large proportion of such cases had their blood-stream sterilized and some were apparently cured by prolonged penicillin therapy. However, the results of closure of the ductus had been sufficiently good to make it unjustifiable to use penicillin alone until the drug had been shown to give equally good or better results in cases of valvular infection and this had not been done yet. The speaker had used penicillin on two patients—a boy of 9 in whom penicillin therapy had been started before admission and a girl of 15 who was gravely ill. The boy received a twenty-eight day course of 120,000 units a day which did not prevent his steady deterioration and he died on the table at subsequent operation. The girl also failed to respond after twelve days of treatment and surgery was undertaken as an emergency as a fatal outcome seemed imminent: this child survived operation and had remained free from her infection for six months although she was still seriously ill from a chronic serous pericardial effusion of unknown cause.

Symptoms or signs of cardiac failure were regarded as indications for operation. In addition, enlargement of the heart or a diastolic pressure below 60 were thought to foreshadow failure at a later date and were therefore grounds for surgical treatment. Retarded development in childhood was likewise an indication.

Finally the question arose as to whether the indications should be enlarged to include all cases. The speaker had felt that the wisest approach was to select those with more definite indications until the operation had been shown to carry a low operative risk but he thought that this had now been done and that Mr. Hunter's series confirmed this. He was therefore now of the opinion that all cases should be closed surgically at about the age of 7. If this were accepted, it was essential that the operation should be done only by those who had studied the problem thoroughly, otherwise there would be some terrible tragedies in apparently fit children.

Preparation for operation in the uncomplicated case was not thought necessary. If infection was present a sulphonamide was given for five days before operation in order to reduce the fever: if it failed to do so, penicillin might be tried for a similar period and with the same object.

An intravenous "drip" was started before operation in case of severe accidental hæmorrhage but this was discontinued as soon as the operation was completed as the burden on the heart would be augmented by the infusion of fluids in the absence of blood loss.

An anterior approach through the second intercostal space had been used in the first 17 cases. In the last case (18) a postero-lateral thoracotomy through the fourth space had been employed in order to compare the two methods; in the speaker's view the latter method definitely gave wider exposure and much more room for manipulation and he proposed using it in all subsequent cases.

With regard to isolation of the ductus, it was important to recognize a finger-like process of serous pericardium which often overlapped the anterior part of the pulmonary end of the ductus: this process should not be opened but should be stripped off the ductus towards the heart by blunt dissection: if opened, the constant leak of pericardial fluid obscured the field. Patience and gentleness were the passwords to success in the

Fifteen patients in all have been operated on, two infected—both female—neither of whom recovered, and 13 non-infected, 9 females and 4 males; these made an uninterrupted recovery with the exception of one female whose case is detailed above, who died of infective endocarditis.

The follow-up shows that both the adults and children are more robust and in better general health than before. It would be fair to say that they were unaware until after the ligation of the ductus what limitations had been imposed on them because of their disability. We shall not for many years know the ultimate fate of these patients; we can only say that by ligating the ductus we have reduced their chances of getting a bacterial endocarditis.

Mr. O. S. Tubbs said that Mr. Hunter's series of cases exemplified the much better results obtainable by treating these patients before complications had arisen. In his own 18 cases treated surgically, infection had been present in 12, early heart failure in 3, retarded development in 2, and absence of secondary effects in only 1. The results of treatment in the infected cases compared unfavourably with the uninfected series presented by Mr. Hunter.

He thought that Mr. Hunter's novel suggestion that the blood flow in a patent ductus during post-natal life was from the pulmonary artery into the aorta could not be maintained although it provided a ready explanation for the surprising cure when infection was present. There appeared to be ample evidence in support of the classical view that the blood flow was from the aorta into the pulmonary artery, e.g. (1) in uncomplicated cases there was no cyanosis which would be present if venous blood were sucked into the aorta from the pulmonary artery; (2) the low diastolic pressure usually associated with patency of the ductus was readily explained by the classical view but very difficult to understand if the blood flow were in the reverse direction. He had in fact regarded the diastolic pressure as inversely proportionate to the calibre of the ductus; (3) pulmonary congestion due to the overloading of the pulmonary circulation from the aorta was often found several years before other signs of heart failure developed; (4) dilatation of the pulmonary artery, sometimes with actual aneurysm formation (an X-ray film depicting such an aneurysm was shown), was commonly present due to the raised pressure caused by the flow from the aorta; (5) the oxygen content of blood removed from the pulmonary artery at operation had been shown by Eppinger and Burwell (1940) to be abnormally high; (6) pulmonary infarction always preceded systemic embolism when subacute endarteritis had complicated the picture; and (7) the irrefutable evidence of cardioangiography whereby Steinberg *et al.* (1943) had shown that none of the relatively concentrated dye in the pulmonary artery was seen to enter the aorta.

In reference to the symptoms of persistent patency of the ductus arteriosus, the speaker agreed that retarded development had been overstressed, for 20 out of 23 patients with a patent ductus whom he had seen during the last six years were of average development. Shapiro and Keys (1943) had also noted that only 1 of their series of 23 had appeared underdeveloped.

Symptoms due to heart failure were uncommon before adult life and occurred more frequently where the calibre of the ductus was large, i.e. in cases with a very low diastolic pressure. Breathlessness and orthopnoea often preceded other symptoms of congestive failure owing to the overloading of the pulmonary circulation. X-ray films of the chest of a girl of 15 with gross enlargement of the heart and congestion of the lung fields were shown and followed by similar pictures taken eight weeks after the operation in which the congestion of the lung fields was no longer seen and the heart shadow had diminished considerably in size.

Bacterial infection, causing fever and, sooner or later, pleuritic pain, might arise at any time and without regard to the calibre of the ductus. It was, however, said to be rare before puberty and have its maximum incidence between 16 and 25, but 2 of his 12 infected cases were aged 9 and 10 respectively so that it was clear that too much reliance should not be placed on youthfulness as a protection against infection. The incidence of infection was difficult to determine as most of the available statistics were based on autopsy findings, but it was probably in the region of 30%. Dental extraction had been the precipitating cause of the infection in two of his patients; it was therefore most unwise to consider dental extraction as a minor procedure in a patient with a patent ductus: if the removal of a tooth were essential it should always be accompanied by sulphonamide therapy.

He wished to emphasize that the work should only be done in co-operation with a cardiologist. Dr. Geoffrey Bourne had been his adviser in all cases.

Maude Abbott (1926) had stated that the diastolic fraction of the characteristic murmur might be absent in children but he had never seen such a case, and Hubbard (1944) and

Acute Rheumatism in Military History

By J. ALISON GLOVER, C.B.E., M.D., F.R.C.P.

ACUTE rheumatism influences war and preparations for it in five main ways:

(1) It is the cause of a proportion of medical casualties in armies in the field, requiring prolonged treatment.

(2) By its incidence in the form of post-tonsillitis barrack epidemics it may disturb training, and ruin for active service previously healthy recruits.

(3) It is the cause of invalidings from the Services and of pension claims, by reason of consequent heart disabilities.

(4) By causing organic heart disease in children it diminishes the pools of man and woman power for recruiting.

(5) It may be the precursor of more chronic forms of rheumatic disease, to which armies in the field are particularly prone, especially fibrositis, lumbago and sciatica.

It is peculiarly fitting to the theme of this paper that it was the great Thomas Sydenham, a "Puritan captain of horse" "a trooper turned physician" as his few detractors called him, who, in 1683, distinguished acute rheumatism from gout and separated the acute from the chronic forms. Nineteen years before this (1664) De la Martinière had described gonorrhœal rheumatism, a disease which has accounted for some of the so-called acute rheumatism in the earlier estimates, for up to 1860 and later the military attack rates of venereal disease were often incredibly high.

I. ACUTE RHEUMATISM AS A CAUSE OF MEDICAL CASUALTIES IN CAMPAIGNS

The epidemiology of rheumatic fever has long suggested its specifically infectious nature, and, in view of its age incidence, and the fact that its onset is traditionally favoured by damp, exposure, wet clothing and privation, it would seem likely to be prominent among those diseases, which dog the train of war, and which so often take a toll of armies in the field far greater than do wounds or death in battle.

rest of the process of isolation. Like Mr. Hunter, he felt that most reports were too generous in estimating the length of the ductus and he had seen several autopsy specimens in which there was almost no length at all. He had met one such "window-type" of ductus in a child of 9—an uninfected case—and, in the attempt to find a way round, considerable hæmorrhage, probably from the back of the pulmonary artery, had occurred. Fortunately the bleeding stopped spontaneously but it was thought wise to make no further efforts to complete the operation and the child was returned to the ward without the object of the operation being achieved. No ill-effects ensued.

The means whereby permanent closure of the ductus might be invariably obtained was the most outstanding problem of all. Out of 12 patients who were now well following ligation 3 (2 infected cases and 1 with heart failure and a duct of the largest calibre he had yet seen) subsequently had a recurrence of a diastolic murmur which indicated a leak. In spite of complete relief from the symptoms and signs of failure in the one and the cure of the infection in the two infected cases it was begging the point to say that the diastolic murmur was of no consequence for these patients were almost certainly still candidates for infection or reinfection. In view of Gross' (1944) report of 14 consecutive successful cases treated by division between clamps and a further 12 successful divisions by Crafoord *et al.* (1944), this ideal should become the aim in many, if not all, cases.

Closure of the ductus always resulted in an immediate rise of diastolic pressure if this were abnormally low. Frequently the diastolic pressure rose further during the first twenty-four hours after operation without a corresponding rise in the systolic pressure so that the pulse pressure was decreased and the pulse felt "thin," but final adjustment to a normal figure usually followed before the patient left hospital.

The effect of successful ligation in infected cases was most dramatic for the fever immediately abated, although occasionally pulmonary emboli causing sudden transient fever occurred during the first two weeks. The blood became almost or completely sterile within a matter of minutes. The reason for these changes was not yet known.

In conclusion the speaker stated that the results might appear gloomy at first sight but he found encouragement in the fact that there had been no death amongst his uninfected cases and that 7 of the infected patients, who in the absence of operation would now be dead, were still alive.

Dr. A. E. Barclay presented a short account of some of the researches that he and his colleagues at the Nuffield Institute for Medical Research, Oxford, had carried out on the foetal circulation, in so far as these related to the ductus arteriosus. In some of this work they had had the collaboration of Sir Joseph Barcroft and Dr. D. H. Barron of Cambridge. Sheep, close to full term, were used, the foetus being delivered by Caesarean section. For the initial stage of each experiment foetal conditions were maintained as closely as possible; a nose-bag containing amniotic fluid was applied over the muzzle of the foetus, and the utmost pains were taken to avoid any obstruction to the placental flow through the umbilical cord. For subsequent stages the nose-bag was removed and the umbilical cord divided between ligatures. For the study of the ductus arteriosus radio-opaque media were injected into the external jugular vein, and records of the flow of these materials through the heart and great vessels were obtained by means of cineradiography. The technique was very complex, nevertheless records of the circulation were obtained in some instances within half a minute of delivery. The times of all procedures, including the cineradiographic records, were recorded on a smoke drum.

Dr. Barclay showed lantern slides taken from some of the cineradiographic records, illustrating in the same animal the course of flow from the superior vena cava under foetal and post-natal conditions respectively, i.e. with the ductus arteriosus patent and functionally closed. In healthy animals functional closure of the ductus took place within a few minutes of removal of the nose-bag and ligation of the umbilical cord. If the condition of the animal deteriorated there was a tendency for the ductus to reopen. Post-mortem observations were found to be quite unreliable as to the conditions obtaining in life. In the sheep foetus the ductus arteriosus is large, its calibre approximating to that of the aorta. The flow through the ductus was consistently from the pulmonary trunk to the aorta; there was no indication of any tendency to a flow in the reverse direction. In the experimental records functional closure of the ductus arteriosus took place after functional closure of the foramen ovale.

- (4) By causing organic heart disease in children it diminishes the pools of man and woman power for recruiting.
- (5) It may be the precursor of more chronic forms of rheumatic disease, to which armies in the field are particularly prone, especially fibrositis, lumbago and sciatica.

It is peculiarly fitting to the theme of this paper that it was the great Thomas Sydenham, a "Puritan captain of horse" "a trooper turned physician," as his few detractors called him, who, in 1683, distinguished acute rheumatism from gout and separated the acute from the chronic forms. Nineteen years before this (1664) De la Martinière had described gonorrhœal rheumatism, a disease which has accounted for some of the so-called acute rheumatism in the earlier estimates, for up to 1860 and later the military attack rates of venereal disease were often incredibly high.

I. ACUTE RHEUMATISM AS A CAUSE OF MEDICAL CASUALTIES IN CAMPAIGNS

The epidemiology of rheumatic fever has long suggested its specifically infectious nature, and, in view of its age incidence, and the fact that its onset is traditionally favoured by damp, exposure, wet clothing and privation, it would seem likely to be prominent among those diseases, which dog the train of war, and which so often take a toll of armies in the field far greater than do wounds or death in battle.

But this is not the case. Its role is a much more modest one. It finds no place in Hurst's *Diseases of War* and the various *Bulletins of War Medicine* make hardly a reference.

Even when the disease was far more common and severe in civil practice than it is to-day, its incidence in armies in the field was much below expectation. Thus in the American Civil War of 1861-4 [3c] we find: "The war records, compared with those of our Army before and since the war, do not show any increased prevalence of rheumatism." And: "Certain it is that we often see regiments exposed to damp, wet, cold, sudden and violent changes of temperature, and obliged to sleep on wet ground with but scant protection, and no cases of acute rheumatism" (Lehlbach, 1863). Nevertheless, rheumatic fever, if not as prominent among war diseases as we might expect, still causes no small proportion of medical casualties.

Campaign of Dettingen.—The earliest statistical information as to the incidence of acute rheumatism in a British and allied force in the field I owe to Sir John Pringle [1].

History repeats itself, and a British and allied force, the so-called "Pragmatic Army", leaving its winter quarters in Brussels in February 1743, marched into Germany, and was cantoned at Aachen and Julich, after experiencing its share of a widespread epidemic of influenza, and on May 17 encamped on the Maine in an open and healthful country. After three weeks of hot days and cold nights the "flying hospital" at Nied had 250 sick [1]. When the number had reached 220 the distempers had been classified and 51 were suffering from "rheumatic pains with more or less of fever". The Army numbered about 14,500 so the attack rate was about 3.5 per 1,000. Later in the summer the disease decreased, and became insignificant compared with dysentery and other intestinal diseases. On June 26 the Army, led by George II in person, won the battle of Dettingen.

Most of the cases were not of the very acute type, and it may be assumed that many myalgias were included, as has happened in more recent wars (*vide* Copeman *infra*).

Pringle clearly distinguishes between acute and more chronic rheumatism, points out the winter-early-spring maximum, and the importance of dry upland camping grounds. He considers most military sciaticas to be rheumatic, and found a "cold bath and riding" regime efficacious in the convalescence from some forms of chronic rheumatism.

It was in the Dettingen campaign that Pringle persuaded the Earl of Stair to propose to the French C. in C., the Duc de Noailles, that hospitals should not be fired upon. The Duke readily consented and ordered that his artillery should not fire on the village of Feckenheim, three miles from Hanau, in which the English field hospital was then lying with some 1,500 sick, mainly dysentery and typhus. This agreement was honoured by both sides throughout the rest of the campaign, thus anticipating the Red Cross movement (Henri Dunant, 1864) by a hundred and twenty-one years.

Pringle, who was also principal medical officer in the 1745 campaign ending in Culloden, came to London in 1748, was physician in ordinary to the Queen and F.R.C.P. in 1763. He was President of the Royal Society and an intimate friend of Captain Cook. His great work *Observations on the Diseases of the Army* (1752), with its modern appreciation of ventilation and space in hospitals and of hygiene generally, alone would secure him his celestial seat among the immortals of our illustrious profession, but his merits as a rheumatologist seem hardly to have been recognized.

I have found no military records of rheumatic fever in the Napoleonic wars. Even in the ill-fated *Walcheren* expedition of 1809, in which conditions might have been thought to favour a high incidence, and though 332 out of every 1,000 died of disease compared with 16 per 1,000 killed or died of wounds, I find no reference to rheumatic fever, so completely was it overshadowed by malaria and typhus fever. Things were very different as regards the ratio of disease and battle deaths one hundred and forty-two years later when our sons fought there once again.

Table I summarizes estimates from the various official histories of recent wars, estimates which are seldom strictly comparable. Those relating to the American Civil War of 1861-4 are especially misleading for, as the authors frankly point out, the contrast between the large incidence and the low death-rate, together with the low case-mortality, at a time when the latter in civil hospitals was about 3%, alike suggest that in this war the majority of cases assigned to acute rheumatism were in fact cases of fibrositis, myalgia or conditions other than acute rheumatism. Bearing in mind

TABLE I.—ACUTE RHEUMATISM IN MODERN CAMPAIGNS.

	Average annual incidence per 1,000 strength	Acute rh. admissions as a percentage of all non-battle admissions	Death-rate per 1,000 strength	Case-mortality %
Crimæa (British) 1854-6	24.5	3.2	1.16	4.7
American Civil 1861-4				
Union Army (Whites)	65.3*	4.7	0.20	0.44

* Much inflated with cases of muscular rheumatism, &c. [3b and c].

† Based on 1,984 cases in Richmond (Van.) (Chimborazo Hospital) [3a].

Copeman's ratio of 15% already referred to, it probably would be safe to divide the incidence of 65 per 1,000 by five or six.

The *Crimean campaign*, as everyone knows, was, in its first year, terribly mishandled. It began far too late in the autumn of 1854. There were great privations, severe exposure to frightful weather and much overcrowding. Great epidemics of cholera and typhus swept the armies, which, in the official medical history [2]—the first of its kind—so overshadow the canvas that one finds only two or three casual references to rheumatic fever in the "observations" and none in the texts of the regimental histories. It is only from the statistical returns that I have extracted the following facts. I was astounded to find that the case-mortality for the cases of chronic rheumatism, 6%, was higher than that for acute rheumatism, 4.3%. For the three months, December 1854, January and March 1855, the case-mortality of chronic rheumatism was nearly 19% compared with 12.2% for acute rheumatism and in one month, February 1855, the case-mortality ascribed to chronic rheumatism reached the astounding figure of 74.2%. I have, therefore, assumed in estimating the incidence, percentage of total admissions, death-rate and case-mortality, for *this war only*, that "chronic rheumatism" was here used to denote "subacute rheumatism" and have therefore included 1,135 cases (with 69 deaths) admitted for chronic rheumatism together with the 3,771 cases (with 163 deaths) admitted for acute rheumatism. Total admission for all diseases (excluding battle casualties) numbered 162,673. More than three-quarters of all the deaths occurred during the fearful weather of the three months of the "Crimean winter" of 1854-5 [2]. This followed close upon the great storm of November 14-15, in which eight ships bringing warm clothing, medical stores and food, sank and nearly all tents, hospital and other, and even huts were blown down. Both November and December were very wet and snow fell heavily. The case-mortality during these three months was 12.2%. From a sample of regimental returns (Table II) which I extracted, the

TABLE II.—CRIMEAN WAR: ACUTE RHEUMATISM IN THE BRITISH ARMY.

Two Years' Returns (from 11.6.1854) from a Large Sample of all Admissions to Hospital from 10 Cavalry Regiments, 3 Guard and 14 Line Infantry Battalions.

Arm	Total admissions for all diseases excluding battle wounds	Admissions for acute rheumatism	% of all medical admissions	Deaths	Case-mortality acute rheumatism
Cavalry	14,402	317	2.2	5	1.6
Guard	9,465	114	1.2	17	14.8

Highest proportion					
1st Battn. 1st (Royal) Regiment	2,317	91	3.9	12	13.2
Highest case-mortality					
3 Gren. Guards	3,196	31	0.97	9	29.0

But this is not the case. Its role is a much more modest one. It finds no place in Hurst's *Diseases of War* and the various *Bulletins of War Medicine* make hardly a reference.

Even when the disease was far more common and severe in civil practice than it is to-day, its incidence in armies in the field was much below expectation. Thus in the American Civil War of 1861-4 [3c] we find: "The war records, compared with those of our Army before and since the war, do not show any increased prevalence of rheumatism." And: "Certain it is that we often see regiments exposed to damp, wet, cold, sudden and violent changes of temperature, and obliged to sleep on wet ground with but scant protection, and no cases of acute rheumatism" (Lehlbach, 1863). Nevertheless, rheumatic fever, if not as prominent among war diseases as we might expect, still causes no small proportion of medical casualties.

Campaign of Dettingen.—The earliest statistical information as to the incidence of acute rheumatism in a British and allied force in the field I owe to Sir John Pringle [1].

History repeats itself, and a British and allied force, the so-called "Pragmatic Army", leaving its winter quarters in Brussels in February 1743, marched into Germany, and was cantoned at Aachen and Julich, after experiencing its share of a widespread epidemic of influenza, and on May 17 encamped on the Maine in an open and healthful country. After three weeks of hot days and cold nights the "flying hospital" at Nied had 250 sick [1]. When the number had reached 220 the distempers had been classified and 51 were suffering from "rheumatic pains with more or less of fever". The Army numbered about 14,500 so the attack rate was about 3.5 per 1,000. Later in the summer the disease decreased, and became insignificant compared with dysentery and other intestinal diseases. On June 26 the Army, led by George II in person, won the battle of Dettingen.

Most of the cases were not of the very acute type, and it may be assumed that many myalgias were included, as has happened in more recent wars (*vide* Copeman *infra*).

Pringle clearly distinguishes between acute and more chronic rheumatism, points out the winter-early-spring maximum, and the importance of dry upland camping grounds. He considers most military sciaticas to be rheumatic, and found a "cold bath and riding" regime efficacious in the convalescence from some forms of chronic rheumatism.

It was in the Dettingen campaign that Pringle persuaded the Earl of Stair to propose to the French C. in C., the Duc de Noailles, that hospitals should not be fired upon. The Duke readily consented and ordered that his artillery should not fire on the village of Feckenheim, three miles from Hanau, in which the English field hospital was then lying with some 1,500 sick, mainly dysentery and typhus. This agreement was honoured by both sides throughout the rest of the campaign, thus anticipating the Red Cross movement (Henri Dunant, 1864) by a hundred and twenty-one years.

Pringle, who was also principal medical officer in the 1745 campaign ending in Culloden, came to London in 1748, was physician in ordinary to the Queen and F.R.C.P. in 1763. He was President of the Royal Society and an intimate friend of Captain Cook. His great work *Observations on the Diseases of the Army* (1752), with its modern appreciation of ventilation and space in hospitals and of hygiene generally, alone would secure him his celestial seat among the immortals of our illustrious profession, but his merits as a rheumatologist seem hardly to have been recognized.

I have found no military records of rheumatic fever in the Napoleonic wars. Even in the ill-fated *Walcheren* expedition of 1809, in which conditions might have been thought to favour a high incidence, and though 332 out of every 1,000 died of disease compared with 16 per 1,000 killed or died of wounds, I find no reference to rheumatic fever, so completely was it overshadowed by malaria and typhus fever. Things were very different as regards the ratio of disease and battle deaths one hundred and forty-two years later when our sons fought there once again.

Table I summarizes estimates from the various official histories of recent wars, estimates which are seldom strictly comparable. Those relating to the American Civil War of 1861-4 are especially misleading for, as the authors frankly point out, the contrast between the large incidence and the low death-rate, together with the low case-mortality, at a time when the latter in civil hospitals was about 3%, alike suggest that in this war the majority of cases assigned to acute rheumatism were in fact cases of fibrositis, myalgia or conditions other than acute rheumatism. Bearing in mind

diseases which included 1,076 cases of "rheumatism", 229 of myalgia and 18 of lumbago.

For 1916, 1917 and 1918 a sampling inquiry [6e] covered 18.5% of all admissions to hospital. Admissions for rheumatic fever formed 3.3% of the total admissions for all diseases and non-battle injuries. The rates for the same three years for troops in the United Kingdom were respectively 3.72, 2.24 and 1.46 per 1,000. The last is much the same as the estimated attack rate (1.53 per 1,000) for rheumatic fever in insured civilian males (16-24) in England and Wales in 1922 [8]. The 1917 incidence coincides with the American rate for troops.

American experience in the First Great War [5], April 1, 1917, to December 31, 1919.—There were 23,818 cases of rheumatic fever; the average annual admission rate was 2.2 for troops in the United States and France; the death-rate, 0.01 per 1,000, and the case fatality 0.18%.

During and immediately after the first Great War the military hospital admissions rate for acute rheumatism fell greatly and has since remained low, the Forces sharing with the civil community in the great and continuous reduction in the incidence and severity of rheumatic fever. The peacetime Army admission rate fell from 4.3 in 1913 to 1.7 in 1927; that of the Royal Navy from 7 per 1,000 to 1.7 for the same years. In 1927 the R.A.F. admission rate was 0.9. The American Army rate fell from 6.2 in 1913 to 1.1 in 1922.

The original *British Expeditionary Force* of 1939-40 which evacuated from Dunkirk had but little rheumatic fever. Copeman [7] records that during the first four months of this campaign admissions to base hospitals No. 2 and No. 3 for "rheumatic" conditions were about 15% of total admissions and 26% of all admissions in the medical division. But only 15% of these patients with "rheumatic conditions" (judging by the first 100 cases admitted to a special "rheumatism" ward) suffered either from acute or subacute rheumatic fever; the great majority—70%—suffered from fibrositis; 6% from rheumatoid arthritis and 9% from osteoarthritis (mostly traumatic in origin). Rheumatic fever therefore seems to have accounted for some 2.25% of total admissions to hospital.

Admission to E.M.S. hospitals from the Services.—Judging by the one-fifth samples taken by the E.M.S. Statistical Branch, Ministry of Pensions, Norcross, the numbers of patients from the Forces admitted to the E.M.S. hospitals [9] in this country with acute rheumatic fever in 1942 and 1943 show that the incidence was low, and that it was heavier in the first half-years than in the second half-years in each case, and that the proportion which rheumatic fever bears to the rheumatic group as a whole is not unlike that found in France by Copeman.

II. BARRACK OR TRAINING CENTRE EPIDEMICS OF ACUTE RHEUMATISM

Training centres often present the following features—a community of susceptible age rendered the more susceptible by sudden transference from home conditions to a strenuous regime, a rapid continuous influx of new entrants, sleeping quarters each containing many persons and overcrowded. At the appropriate season, the carrier rate of one particular (the "epidemic") strain of *Streptococcus pyogenes* rises, an epidemic of acute tonsillitis appears, and, a little later, cases of acute rheumatism, often in a ratio of about 1 to every 10 cases of acute tonsillitis [12]. Surgeon Commander C. A. Green [10] has reported one where the attack rate of rheumatic fever rose to 63 per 1,000. The recognition of this phenomenon is a matter of recent history, but if we look back some of the old records strongly suggest that it has often occurred before. Thus in 1859, when acute rheumatism admission rates in the Army were still high, that for depot battalions was 65.4 per 1,000, more than twice that for the Foot Guards, 31.7. It is recorded that "Many of the cases were the sequel of venereal disease" so the incidence shown is probably too high. The great differences in incidence [5] for white troops between the 32 training camps in the United States in 1917-19 suggest the probability of "barrack epidemics" in some of them. The average incidence for all these camps was 8.4 per 1,000, the highest 31.5 at Camp Cody, and the lowest 4.3 at Upton Camp. Table III shows some of the highest and the lowest but I have no information as to overcrowding or other features.

G. C. Ferguson (1943) describes a sudden increase in admissions to military hospitals in Canada for acute rheumatism in February, March, April and May 1942; 331 cases

Guards' case-mortality seems to have been ten times that of the cavalry who, not being in the trenches, were less exposed, and nearly three times that of those line battalions which are included in the sample. Perhaps the rigid discipline of the Guards kept the patients so long in the trenches after the onset of the disease that their recovery was prejudiced.

In this war the average annual incidence is more than usually misleading, calculated as it is on a strength of 98,000, for, at the beginning of the peak period, death, wounds and disease had reduced the effective strength to 24,000. In considering the high case-mortality, however, we must remember that in those days the average case-mortality in civil hospitals was reckoned as high as 3% (Loumis) [3c], and that in 1837 Macleod considered rheumatic fever "not only one of the most prevalent but one of the most fatal maladies incident to our precarious climate".

The fallacies of the *American Civil War* figures for the incidence of acute rheumatism have already been pointed out; and I regard the only figure worthy of credence to be the Confederate case-mortality which comes from a series of 1,984 cases "with known results" in the Chimborazo Hospital, Richmond, Virginia [3a]. The observations of the authors are, however, admirable and I have already quoted two extracts showing the unexpected rarity of the disease. A third acute observation is that: "Acute rheumatism shows in its monthly rates a greater prevalence in that period of the war during which new levies were sent to the field than later when the levies have become inured to the hardships of active service."

South African War 1899-1902.—In this campaign, characterized more by heavy marching on half rations than by severe battle casualties, the outstanding medical phenomena were the vast epidemics of typhoid and dysentery. But the admissions for rheumatic fever [6b] formed 6.05 of the total admissions for all diseases and non-battle injuries, and, during the whole war, amounted to 24,460, thus exceeding those for wounds, 21,292. The total killed and wounded was 27,273. The average annual admission rate was 44 per 1,000, the death-rate 0.04 per 1,000, and invalided 7.75 per 1,000. The case-mortality was 0.1%, half that of the American Civil War. If, however, the cases and deaths from *valvular disease* be included the case-mortality is 0.37%, which is doubtfully comparable with the American composite figure of 0.44 quoted above.

Why was there more rheumatism in the high and healthy climate of South Africa than in the mud of the trenches of 1915? One reason seems to have been that acute rheumatism had already begun to decline in incidence and severity. The heavy marching may have been an important factor in this war, and one often out-marched one's ox-drawn rations. Describing the march to Pretoria the author of the official military history [4] writes [The heavily laden infantry] "averaged nearly seventeen miles a day over apparently endless prairies in blazing sun and bitter cold, swept now by hot and choking dust storms, now by rushes of icy hail, fording rivers and floundering through sand, with scanty food and shelterless bivouacs, their toil had been almost unlightened by anything but hope. . . . On the vast levels there was nothing to be seen but their own long ranks, no sound to be heard but that of their own footsteps. Silence attended their marches, hunger, fatigue and discomfort their nightly sleeping places."

Great War 1914-19.—That rheumatic fever was less prevalent in France in 1915 with all its mud than in the magnificent climate of South Africa seems confirmed by the fact that after four years of trench warfare Colonel T. Hay [6a] wrote "acute rheumatic fever was not a common disease among soldiers in France, and it is improbable, therefore, that much valvular disease of the heart originated during war service". The vast majority of joint and limb pains in this war were due to trench fever and other non-rheumatic conditions.

It was not found practicable to deal with the medical casualties of the later years in the same detail as was done in 1915, and rheumatic fever is not included in the "principal recorded causes" of admission to hospital from the British Expeditionary Force in France for 1916 onwards.

In Italy [6d] the disease seems to have been very rare in British troops, 72 cases of rheumatic fever being admitted, thus making only 5.2% of the rheumatic group of

Cardiac Folk-Lore

By J. D. ROLLESTON, M.D., F.R.C.P., F.S.A.

INTRODUCTION

It is generally agreed that a scientific study of heart disease did not begin until the seventeenth century. It is not surprising, therefore, that a vast amount of cardiac folk-lore developed and persisted for several centuries. Although the doctrine that lesions of the heart are generally fatal has been wrongly attributed to Hippocrates, it is undoubtedly of great antiquity. According to Hovorka and Kronfeld [1a] there is hardly a trace in classical literature of the severe cardiac diseases which subsequently played such an important part in scientific medicine, and the chief cardiac affections recognized before the beginning of the nineteenth century were merely palpitation and pain in the cardiac region.

Parrot [2] remarks that this ignorance of heart disease in antiquity may seem strange in view of the fact that other affections of less importance were thoroughly studied in ancient times, and suggests that the only explanation of this omission was that the heart was regarded as a sacred organ which it was wrong to touch and study. According to Moon [3] Aristotle, though he did not think the heart was exactly invulnerable, said that it was the only one of the viscera, and indeed of any part of the body, that was unable to tolerate any serious affection.

Parrot remarks that even in the time of Erasistratus and Asclepiades knowledge of the heart was so vague that the word *καρδία* was applied to both the heart and the stomach, which was doubtless due to the juxtaposition of the two viscera separated only by the diaphragm. This confusion, says Parrot, seems to have lasted down to the present day, when a trace of it survives in the expression *mal de cœur* indicating transient gastric disturbance. According to Paulus Aegineta [4] "when the heart itself is primarily affected, the case is far beyond all medical aid, occasioning sudden death; and so also in the inflammation and erysipelas of it, strong distemperatures in very acute fevers, and hæmorrhage when it is wounded, especially in the left ventricle. When the heart is affected sympathetically with the brain, the liver, the orifice of the stomach and from sorrow, fever and many other causes, it brings on the affection called syncope, being a sudden collapse of strength, *deliquium animi*, a small pulse, coldness of the extremities and copious perspiration".

In his recent work on the history of cardiology Herrick [5] discusses the meaning of the term *morbus cardiacus* used by Celsus and other Roman writers, lay as well as medical, and after referring to the article by Landsberg [24] comes to the conclusion that several conditions were described, viz. pericarditis, cardiac failure with irregularities, angina pectoris, coronary thrombosis, gall-bladder conditions, disease of the stomach such as ulcer, acute infections of different types and what would be called to-day cardiac neurosis and psychoneurosis.

Ætiology.—According to Hovorka and Kronfeld [1b] cardiac palpitation has been variously attributed to viscosity of the blood, a worm gnawing the heart and a stone embedded in this organ. The last view but one is upheld by the Germans in Western Bohemia who kill the worm and destroy its nest by administration of fresh scabious juice and watercress, followed by substances which dissolve the stone, such as plaster of strong spirit and rye flour.

Among the factors mentioned by the Physicians of Myddvai [6a] as being harmful to the heart are onions, peas, cummin, garlic, sorrow, anger, too much care, too much travelling, drinking cold water after a journey and bad news. On the other hand: "If a man wisheth health and long life let him carefully maintain a merry heart, let him neither eat, drink nor do what will harm it, for as the wise man says—'A merry heart and all is well'."

Phraseology.—The following popular phrases connected with the heart are quoted by Rorie [7a] as prevalent in Scotland: To *gar the heart rise* is to make sick. To *gar the heart fall* is to affect almost to tears; the heart is *gay near the mouth* means the same.

TABLE III.—1917-1919 ACUTE RHEUMATISM (WHITES ONLY).

Variations in the Incidence in the 32 Training Camps of the U.S. Army. That these variations are not mainly climatic or geographic is suggested by comparison with the attack-rates in the States in which the Camps were respectively situated, but on other soldiers, who were not in the Training Camps.

Average attack-rate for enlisted men in U.S.: 8.12 per 1,000. Average attack-rate for whole U.S. Army and Europe: 6.43.				
Camp	Mean annual strength	Camp attack-rate per 1,000	State in which camp was situated	Attack-rate per 1,000 on non-camp soldiers in State
<i>High rates</i>				
Cody	22,636	31.5	New Mexico	8.50
Pike	40,869	19.4	Arkansas	8.82
Doniphan	26,747	18.4	Oklahoma	3.71
Funston	50,054	17.1	Kansas	29.40
Mean of all 32 camps.		8.4		
<i>Low rates</i>				
Lec	51,004	5.2	Virginia	4.22
Lewis	47,267	4.0	Washington	8.33
Upton	40,202	4.3	New York	6.9

Extracted from Vol. XV, Part 2, Med. Dep. U.S. Army in World War I.

were admitted in these four months, and 534 in the year ending July 31. This prevalence seems probably to have been due to something like "barrack epidemics", for 78% of the patients were between 18 and 25 years. The high carrier rate of *S. pyogenes* was shown by concurrent epidemics of scarlet fever and tonsillitis. The article demonstrates the military need (a need which has been particularly felt in the United States recently) to prevent such epidemics of acute rheumatism, for 50% of the patients were invalided out of the Service (including 35% with valvular disease and 7% with rheumatoid arthritis) while of the 50% who returned to duty, a further 20% were later invalided.

All statistics relating to acute rheumatism are difficult but to try to compare "invaliding" in the various wars leads only to a morass of differing phrases and differing meanings of the same phrase. It is clear, however, that the rates have greatly diminished in the last ninety years. I cannot hazard a guess for the Crimea. In the American Civil War the ratio was 25.1 per 1,000; in South Africa 7.75; in the first World War I estimate the figure at 8.2 per 1,000 but I do not think that this estimate relates so accurately to acute rheumatism as does the South African figure; it probably includes other forms than acute. It is yet too early for estimates for the Army in the present war. Surgeon Commander Green, however, tells me that in the one year 1944 in the Navy 0.26 per 1,000 were invalided for rheumatic fever with or without cardiac lesions, and an additional 0.08 invalided for allied cardiac conditions, making 0.36 per 1,000 (males) strength.

In the short time at my disposal I have tried to show that acute rheumatism, never acting a conspicuous part in military history, has always been an insidious foe especially to the recruit in training. Fortunately it appears an obsolescent disease in the Army as it is, as I have elsewhere shown [1], in civil life. This cheering impression of a rapid decline should stimulate our efforts finally to extinguish this Moloch of young life and health.

Cardiac Folk-Lore

By J. D. ROLLESTON, M.D., F.R.C.P., F.S.A.

INTRODUCTION

It is generally agreed that a scientific study of heart disease did not begin until the seventeenth century. It is not surprising, therefore, that a vast amount of cardiac folklore developed and persisted for several centuries. Although the doctrine that lesions of the heart are generally fatal has been wrongly attributed to Hippocrates, it is undoubtedly of great antiquity. According to Hovorka and Kronfeld [1a] there is hardly a trace in classical literature of the severe cardiac diseases which subsequently played such an important part in scientific medicine, and the chief cardiac affections recognized before the beginning of the nineteenth century were merely palpitation and pain in the cardiac region.

Parrot [2] remarks that this ignorance of heart disease in antiquity may seem strange in view of the fact that other affections of less importance were thoroughly studied in ancient times, and suggests that the only explanation of this omission was that the heart was regarded as a sacred organ which it was wrong to touch and study. According to Moon [3] Aristotle, though he did not think the heart was exactly invulnerable, said that it was the only one of the viscera, and indeed of any part of the body, that was unable to tolerate any serious affection.

Parrot remarks that even in the time of Erasistratus and Asclepiades knowledge of the heart was so vague that the word *καρδία* was applied to both the heart and the stomach, which was doubtless due to the juxtaposition of the two viscera separated only by the diaphragm. This confusion, says Parrot, seems to have lasted down to the present day, when a trace of it survives in the expression *mal de cœur* indicating transient gastric disturbance. According to Paulus Aegineta [4] "when the heart itself is primarily affected, the case is far beyond all medical aid, occasioning sudden death; and so also in the inflammation and erysipelas of it, strong distemperatures in very acute fevers, and hæmorrhage when it is wounded, especially in the left ventricle. When the heart is affected sympathetically with the brain, the liver, the orifice of the stomach and from sorrow, fever and many other causes, it brings on the affection called syncope, being a sudden collapse of strength, *deliquium animi*, a small pulse, coldness of the extremities and copious perspiration".

In his recent work on the history of cardiology Herrick [5] discusses the meaning of the term *morbus cardiacus* used by Celsus and other Roman writers, lay as well as medical, and after referring to the article by Landsberg [24] comes to the conclusion that several conditions were described, viz. pericarditis, cardiac failure with irregularities, angina pectoris, coronary thrombosis, gall-bladder conditions, disease of the stomach such as ulcer, acute infections of different types and what would be called to-day cardiac neurosis and psychoneurosis.

Ætiology.—According to Hovorka and Kronfeld [1b] cardiac palpitation has been variously attributed to viscosity of the blood, a worm gnawing the heart and a stone embedded in this organ. The last view but one is upheld by the Germans in Western Bohemia who kill the worm and destroy its nest by administration of fresh scabious juice and watercress, followed by substances which dissolve the stone, such as plaster of strong spirit and rye flour.

Among the factors mentioned by the Physicians of Myddvai [6a] as being harmful to the heart are onions, peas, cummin, garlic, sorrow, anger, too much care, too much travelling, drinking cold water after a journey and bad news. On the other hand: "If a man wisheth health and long life let him carefully maintain a merry heart, let him neither eat, drink nor do what will harm it, for as the wise man says—'A merry heart and all is well'."

Phraseology.—The following popular phrases connected with the heart are quoted by Rorie [7a] as prevalent in Scotland: To *gar the heart rise* is to make sick. To *gar the heart fall* is to affect almost to tears; the heart is *gey near the mouth* means the same.

Great-heartit means emotional. To get round the heart is to cause to feel faint. To gang wi' the heart is to go with one's inclinations.

Treatment.—The folk-lore treatment of heart disease may be considered under general measures, animal cures including coprotherapy in the form of white wine poured on dry fox's dung [1b], plant remedies, hydrotherapy, metals and patron saints.

General measures.—These consist of a strict diet, abstinence from wine, not lying on the back or on the left side in bed, and in burning a night light [1b].

Animal cures.—For beating and palpitation of the heart Moncrief [8a] recommends "chiefly the bone of the Heart of a Hart or Stag made in Powder and taken with Rose water and Wine and the Heart of an Ox steeped in white wine and then distilled". For weakness of the heart Moncrief [8b] gives the following advice: "Boil between two dishes a piece of a leg of mutton after the skin and fat is taken off, and let the patient drink the broth being strained at one draught."

"Boil a Hen, in a Vessel well stopt and covered in all places to the consumption of two parts of the water casting thereto comfortable things such as maces, amber, musk and then apply it to the Patient's Nose, and give the patient the Broth to drink" [8a].

Plant remedies.—There are numerous plant remedies for heart complaints in folk-lore of which the following are those most frequently employed—anchusa officinalis, balm, bugloss, centaury, cinnamon, endive, fennel, galingale, ginger, hyssop, hyoscyamus, pellitory of Spain, plantago, sage, violet and yarrow [1b]. Moncrief [8c] describes the following decoction as "a sovereign Remedy for gnawing about the heart": "Take Sage-Leaves, a pretty quantity, and as much Yarrow and temper them with Ale, then strain them, and you shall presently have relief." For oppression of the heart the Physicians of Myddvai [6b] prescribe as follows: "Take the juice of fennel and honey; boil together till they become hard and eat a portion of the same the first thing in the morning before food, and the last thing in the evening after food. It will cure you by God's help."

Hydrotherapy.—This consists in washing the left side of the chest with cold water and drinking a glass of cold water before going to bed [1b].

Metals.—According to Hovorka and Kronfeld [1b] a gold plate attached to the cardiac region drives away palpitations and makes the patient cheerful.

Patron saints.—In striking contrast with the great majority of diseases, the patron saints invoked for the relief or cure of heart disease are very few in number, being only one for angina pectoris, viz. St. Quitorie [9a], and three for other cardiac diseases, viz. St. Doucre [9b], St. Furzy [9c] and St. Kotska [9d].

Therapeutic and prophylactic action of the heart.—Not only have numerous popular remedies been used in the treatment of various forms of cardiac disease, but in many instances the heart itself in man and animals as well as heart-shaped inanimate objects have been credited with prophylactic and curative properties, of which the following are examples:

Dingwall [10] relates the case of "a man in Kenlochewe, who was told by a wise woman that his cattle suffering from pestilence would only be cured if he got the heart of a man who did not know his parents, dipped it in a bucket of water and sprinkled the cattle with the water. A pedlar came his way shortly afterwards. He murdered him, got his heart, and cured his cattle, but the disease was transferred to his family, and their descendants, with this taint of madness, were to be recognized less than a hundred years ago".

According to Democritus quoted by Pliny [11a] the chameleon's heart attached to the body with black wool of the first shearing is a good preservative against attacks of quartan fever. Democritus [11b] also states that a quartan fever is effectually cured by attaching a crocodile's heart to the body with the wool of a black sheep without a speck of any other colour, due care being taken that the sheep was the first lamb weaned by the dam.

Another cardiac remedy for fever, mentioned by Pliny [11c], is to swallow the heart of a sea-diver removed from the bird without the aid of iron, it being first dried and then bruised and taken in warm water. The heart of a swallow with honey is also recommended, as well as a viper's heart removed from the reptile while still alive [11c].

Seligmann [12] relates that in Ancient Egypt one form of protection against the Evil Eye consisted of a drop of water and the urine of an ape combined with the heart of a jackal, a stalk of grass and the nose of a pig.

It is noteworthy in this connexion that in Roman Catholic countries, and especially Portugal, amulets in the form of a heart are extensively used as a prophylactic agent against the Evil Eye [13].

According to *Arcana Fairfaxiana Manuscripta* [14], of which the subtitle is "A manu-

script volume of Apothecaries' Lore and Housewifery" nearly three centuries old, used and partly written by the Fairfax Family, a cure for the falling sickness (epilepsy) is as follows: "Take the harte of a toade and drie it and beate it to powder; then drinke with what drinke you will."

According to Pliny [11d] "some say that the heart of the lark should be attached to the patient's thigh for the cure of colic and according to others the heart should be swallowed fresh, quite warm in fact. There is a family of consular dignity, known as the Asprenates, two brothers, members of which were cured of colic, the one by eating a lark and wearing its heart in a golden bracelet, and the other by performing a sacrifice".

As regards the prophylactic action of the heart Pliny [11e] quotes the statement that persons who carry the heart of a vulture about them will be safe not only from serpents but from wild beasts as well as robbers and will have nothing to fear from the wrath of kings.

Besides its therapeutic action, there are several other results of the administration of the heart, as is shown by the following examples among the "prodigious lies" of the magicians mentioned by Pliny [11f]: "They pretend that the heart of a horned owl applied to the left breast of a woman while asleep will make her disclose all her secret thoughts."

In this group may be placed those recorded by Bonnerjea [15]: (1) In East Prussia there is a belief that if the heart of an unborn child is carried on the person it is sure to bring about complete success in the thieving profession. (2) The Jews of Minsk believe that if a person eats the heart of a bear he will become a tyrant.

Speaking of the mole, Pliny [11g] remarks that of all animals it is the mole that the magicians admire most. There is no animal in the entrails of which they put such implicit faith. "So much so, indeed, that if a person swallows the heart of a mole fresh from the body and still palpitating, he will receive the gift of divination, they assure us, and a foreknowledge of further events."

In George Wales' *Book of Cures* quoted by Mrs. Gutch [16] we read "if any one swallow the heart of a swallow, or a weasel, or a mole while it is still warm with natural heat, it shall help him for remembering, understanding and foretelling".

Pliny [11h] quotes Democritus to the effect that "if a tongue is extracted from a live frog, with no other part of the body adherent to it, and is then applied—the frog being first replaced in the water—to a woman while asleep, just at the spot where the heart is felt to palpitate, she will be sure to give a truthful answer to any question which may be put to her".

FOLK-LORE SUPERSTITIONS CONNECTED WITH THE HEART

According to Pliny [11k] "it is asserted that the heart cannot be burnt in those persons who die of the cardiac disease and that the same is said of those who die by poison". In support of this view Pliny quotes the case of Vitellius who accused Piso of poisoning Germanicus, and in support of this accusation declared that the heart of Germanicus could not be burnt. On the other hand the peculiar nature of the disease from which Germanicus suffered was alleged in Piso's defence.

Although Pliny's work contains more folk-lore than any of his contemporaries, Moulé [17] suggests that his lack of confidence in many of the remedies he mentions is shown by the frequency with which he uses the words "ut aiunt", "ut tradunt", "dicitur" and "dicuntur" in the description of various remedies.

Another popular belief mentioned by Pliny [11m], for which there does not appear to be any foundation, is that animals with a hard and rigid heart are looked upon as stupid and lumpish, while those in whom it is small are courageous and those with a very large heart are timid.

Casting of the heart.—In Orkney and Shetland according to Black [18] and Gregor [19] the inhabitants firmly believe that if any person is emaciated by sickness or other accidental causes the heart is worn away. The method of determining this is known as *Casting of the Heart* and carried out by melting a piece of lead and throwing it into cold water. According to the shape it takes, so they form their judgment. If it takes the shape of a heart, the person is not altogether gone and will recover.

The heart and insanity.—In Highland therapy as Mrs. Moodie [20] has shown, there was a belief that insanity was caused by a person's heart getting displaced, owing to a sudden shock. It was imagined that a similar sudden shock would replace it in its former position, and that thus the natural balance would be restored. Consequently a sudden shock was one of the old specifics for insanity.

Great-heartit means emotional. To *get round the heart* is to cause to feel faint. To *gang w' the heart* is to go with one's inclinations.

Treatment.—The folk-lore treatment of heart disease may be considered under general measures, animal cures including coprotherapy in the form of white wine poured on dry fox's dung [1b], plant remedies, hydrotherapy, metals and patron saints.

General measures.—These consist of a strict diet, abstinence from wine, not lying on the back or on the left side in bed, and in burning a night light [1b].

Animal cures.—For beating and palpitation of the heart Moncrief [8a] recommends "chiefly the bone of the Heart of a Hart or Stag made in Powder and taken with Rose water and Wine and the Heart of an Ox steeped in white wine and then distilled". For weakness of the heart Moncrief [8b] gives the following advice: "Boil between two dishes a piece of a leg of mutton after the skin and fat is taken off, and let the patient drink the broth being strained at one draught."

"Boil a Hen, in a Vessel well stopt and covered in all places to the consumption of two parts of the water casting thereto comfortable things such as maces, amber, musk and then apply it to the Patient's Nose, and give the patient the Broth to drink" [8a].

Plant remedies.—There are numerous plant remedies for heart complaints in folk-lore of which the following are those most frequently employed—*anchusa officinalis*, balm, bugloss, centaury, cinnamon, endive, fennel, galingale, ginger, hyssop, hyoscyamus, pellitory of Spain, plantago, sage, violet and yarrow [1b]. Moncrief [8c] describes the following decoction as "a sovereign Remedy for gnawing about the heart": "Take Sage-Leaves, a pretty quantity, and as much Yarrow and temper them with Ale, then strain them, and you shall presently have relief." For oppression of the heart the Physicians of Myddvai [6b] prescribe as follows: "Take the juice of fennel and honey; boil together till they become hard and eat a portion of the same the first thing in the morning before food, and the last thing in the evening after food. It will cure you by God's help."

Hydrotherapy.—This consists in washing the left side of the chest with cold water and drinking a glass of cold water before going to bed [1b].

Metals.—According to Hovorka and Kronfeld [1b] a gold plate attached to the cardiac region drives away palpitations and makes the patient cheerful.

Patron saints.—In striking contrast with the great majority of diseases, the patron saints invoked for the relief or cure of heart disease are very few in number, being only one for angina pectoris, viz. St. Quitorie [9a], and three for other cardiac diseases, viz. St. Doucre [9b], St. Furzy [9c] and St. Kotska [9d].

Therapeutic and prophylactic action of the heart.—Not only have numerous popular remedies been used in the treatment of various forms of cardiac disease, but in many instances the heart itself in man and animals as well as heart-shaped inanimate objects have been credited with prophylactic and curative properties, of which the following are examples:

Dingwall [10] relates the case of "a man in Kenlochewe, who was told by a wise woman that his cattle suffering from pestilence would only be cured if he got the heart of a man who did not know his parents, dipped it in a bucket of water and sprinkled the cattle with the water. A pedlar came his way shortly afterwards. He murdered him, got his heart, and cured his cattle, but the disease was transferred to his family, and their descendants, with this taint of madness, were to be recognized less than a hundred years ago".

According to Democritus quoted by Pliny [11a] the chameleon's heart attached to the body with black wool of the first shearing is a good preservative against attacks of quartan fever. Democritus [11b] also states that a quartan fever is effectually cured by attaching a crocodile's heart to the body with the wool of a black sheep without a speck of any other colour, due care being taken that the sheep was the first lamb yeaned by the dam.

Another cardiac remedy for fever, mentioned by Pliny [11c], is to swallow the heart of a sea-diver removed from the bird without the aid of iron, it being first dried and then bruised and taken in warm water. The heart of a swallow with honey is also recommended, as well as a viper's heart removed from the reptile while still alive [11c].

Seligmann [12] relates that in Ancient Egypt one form of protection against the Evil Eye consisted of a drop of water and the urine of an ape combined with the heart of a jackal, a stalk of grass and the nose of a pig.

It is noteworthy in this connexion that in Roman Catholic countries, and especially Portugal, amulets in the form of a heart are extensively used as a prophylactic agent against the Evil Eye [13].

Non-specific Intestinal Granuloma

PRESIDENT'S ADDRESS

By ERIC A. CROOK, M.Ch.

For many years it has been recognized that certain tumour-like formations occur in both large and small intestines which do not conform to any known specific pathology. This group of lesions, showing massive new formations of tissue, was originally put in a separate category from neoplastic conditions and contained in its number lesions which have subsequently, in their turn, been split off from the main mass on the discovery of their specific pathology. A group of undetermined pathology still exists, possibly not all similar in aetiology, for which the term "non-specific intestinal granuloma" appears the best to adopt, as the more generally accepted term "infective granuloma" implies an infective nature of which we have at present no proof.

Before the year 1907 there are occasional references in the literature to tumour formations in the bowel that did not present the features of new growth, but it was in this year that Lord Moynihan described the condition giving details of six cases in a paper entitled "The Mimicry of Malignant Disease of the Large Intestine". Two of these cases involved the rectum, with thickened walls, causing stenosis and ulceration of the mucosa. Two involved the sigmoid colon with tumour formation and "false diverticula". Two affected the transverse colon, forming a hard smooth tumour mass which disappeared after a short-circuiting operation.

In 1909 Braun gave a report on these non-malignant tumours, and in the same year le Dentu described similar cases under the heading of "False Cancers and Inflammatory Tumours of the Abdomen". He subdivided these into groups: (i) interstitial colitis, circumscribed in character and associated with hypertrophy, resulting in a certain amount of stenosis; (ii) simple pericolicitis with adhesions; (iii) diffuse pericolicitis with the formation of an elongated mass; (iv) exuberant pericolicitis, in which form the intestines and extra-peritoneal connective tissue and glands are all matted together.

Isolated cases of tumour formation associated with diverticula of bowel were recorded at this time, and the condition of diverticulitis came to be recognized, with its established pathology, thus detaching itself from the main group of non-specific granulomata. The earliest comprehensive account of diverticulitis is given by Maxwell Telling in 1916,

Displacement of heart and sudden death.—Another effect of cardiac displacement also supposed to occur in the Highlands, according to Rorie [7b], was sudden death, especially in pregnancy or severe scalding in a child. In the case of the mother sudden death was attributed to "the bairn pittin' up its hand and grippin' its mother's heart".

In the mining folk of Fife, according to Rorie [7c], hiccough is supposed to be caused by "a nerve in the heart" and at every hiccough "a drop of blude leaves the heart".

According to Elworthy [21] the County Museum at Taunton contains several hearts studded with pins, said to be those of pigs and found long ago in old houses. Besides being protective the hearts were supposed to possess evil properties and to have a malignant effect on the person in whose house they were found. It was believed that the hated person's heart would suffer from the pricking inflicted upon the pig's heart and that as the latter dried up so would the heart and life of the victim against whom the act was directed.

In his *Vulgar Errors* (IV, 4) Sir Thomas Browne shows that there is no anatomical foundation for the belief that there is a small vein, nerve or artery running from the left finger to the heart. Reference may be made here to the celebrated "Voltaire's Nerve" which is an imaginary nerve running from the brain to the organs of generation via the eyes, lips and heart. As I have suggested elsewhere [22] this conception was not a mere *jeu d'esprit* in view of the fact that the role of the nerves in the economy was still in the realm of nebulous hypotheses in Voltaire's day, and it was not until the time of Charles Bell in 1811 and Magendie in 1812 that the functions of the nerves were well understood.

Eating the heart.—MacCulloch [23] remarks that as the heart is regarded as the seat of life, soul, wisdom and similar virtues, savages devour the hearts of their enemies so that these qualities may pass into them. This practice is sometimes combined with the eating of other parts of the body, especially the liver, which was credited with similar qualities. Some animals, particularly the lion, bear, wolf and certain birds such as hawks or crows, are also treated in the same way for the purpose of transmitting strength, courage, cunning, wisdom, &c.

re of these fistulæ. He gave no explanation of the ætiology of the process, which did fall into any of the recognized granulomatous or accepted inflammatory groups. No circle bacilli were found, and the Wassermann reaction was negative. There were no significant agglutination titres against the various strains of dysentery organisms, and its intradermal test was negative. The disease ran a relatively benign course, and the sufferers who survived operation were restored to good health. He based observations on a study of 14 cases. In his description of the tissue changes, describes the mucosa as presenting a cobblestone appearance, replacing the normal intestinal folds. A series of small linear ulcerations is found in a groove on the mesenteric side of the bowel, which may be remnants of the original ulcerative lesions that led to the bullous change in the mucosa, or possibly mechanical erosions due to the formation of a *Darmstrasse* produced by shortening of the fibrotic mesentery. The mucosa and, to a less extent, the muscular layers of the bowel are the seat of marked inflammatory hyperplastic and exudative changes and the wall of the bowel becomes enormously thickened, and presents the appearance of a hosepipe at operation. In later stages the exudative reaction is replaced by a fibrostenotic process, the mucosa appears opaque with occasional islands of polypoid overgrowth. The serous coat loses its gloss and may have tubercle-like structures on its surface. The mesentery is greatly thickened and fibrotic, and the glands are enlarged. There is a tendency to slow perforation with resulting adhesions and fistulæ, especially to the sigmoid and ascending colon. Walled-off abscesses form which are often thought to be appendicular in origin, and if they are opened they lead to fecal fistulæ. Microscopically, there are no specific features but varying degree of acute, subacute and chronic inflammation, in which giant cells of the foreign-body type may be seen.

Borke and Lee put forward the view that the tissue changes were produced by a secondary involvement of the blood supply, due to lymphangitis, which lead to a slow vitalization of the bowel wall, and recently Reichert and Mathes (1936), struck by a marked œdema and fibrosis of the intestinal wall and lymphatic engorgement present in resected specimens, attempted to reproduce the disease experimentally. They blocked the mesenteric and subserous lymphatics of dogs by injection and gave intravenous injections of *B. coli*. In this way they produced a chronic lymphœdema of the ileum and appearances somewhat resembling Crohn's disease.

Following Crohn's original article, a large number of cases conforming to his description are published in the journals. A case described by Colp (1934) is of interest. The patient, a medical student, was operated on for appendicular colic, and at the time of the operation, appearances of Crohn's disease were noted involving the terminal ileum and cæcum. The appendix and glands were removed and reported by the pathologist to be normal. He derived no benefit from the operation, and returned to hospital in eight weeks when a mass could be felt in the right iliac fossa. This case supports the view that the disease does not only elect and affect the ileum, but may attack the cæcum and other areas of the colon. The ileocæcal valve does not arbitrarily limit the downward progress of the disease affecting the ileum, any more than it limits the upward progress of ulcerative colitis. In the many cases recorded there is great variation in the condition present.

A case of massive intestinal hæmorrhage in Crohn's disease is recorded by Fallis (1941).

In 1939 Crohn accepted the possibility of the condition involving the cæcum as well as the terminal ileum, and of occurring in isolated segments of the colon. He did not consider trauma played a part, and did not incriminate the appendix. He referred to the association of perianal and rectal fistulæ, which he considers occur as a result of infection in the rectal crypts of Morgagni by contaminated fecal material. He mentioned fistula-in-ano as occasionally being the presenting symptom in regional ileitis, before the abdominal lesions could be detected, and he quotes the instance of a house surgeon examining a patient admitted to hospital for operation on fistula-in-ano, and finding a mass which suggested and subsequently proved to be Crohn's disease, previously unsuspected. In the treatment he found that a simple short-circuit operation gave a 50% recovery, so he favoured resection of the affected tissue, carrying this out in one stage, if possible. Resection, however, was sometimes followed by recurrence.

Hadfield (1939) gave an account of the histology of Crohn's disease, considering it to be a lymphadenoid hyperplasia with the formation of non-caseating giant-cell systems in the submucosa. He finds the lesion also present in the lymph glands. Ulceration and fistulæ he considers to be secondary to the lesion in the submucosa, and the obstructive lymphœdema which it produces. Ulceration often obscures and sometimes obliterates the primary lesion in the submucosa, and when this happens he finds that the lesion is not uncommonly present in some or all of the regional lymphatic glands.

and even at this time he comments on the fact that the condition had not yet reached the ordinary students' textbooks of Surgery.

After this, little reference to "granuloma" is found in the literature till 1923, when Moschowitz and Wilensky published an article, "Non-specific Granulomata of the Intestine", describing four cases, three of these in the cæcum and ascending colon, and one at the splenic flexure. In two cases the appendix had been removed previously in a state of acute inflammation, and in the third the appendix showing signs of chronic inflammation was found in the mass. In all three specimens there was a firm tense uncircumscribed tumour, involving all the coats of the intestine, and causing constriction of the lumen. In three cases there were superficial ulcerations of the mucosa. In one specimen the main bulk of the tumour projected into the mesentery. In another specimen a granuloma of the small intestine had developed a year later, after resection of the ascending colon.

Microscopically these cases gave almost identical findings, viz. interstitial infiltration of all the coats of the intestine, with round cells and plasma cells, and there was wide variation of a fibroblastic formation from a comparatively richly cellular tissue to a firm tense fibrous scar. There was new blood-vessel formation. Giant cells were present, especially in the specimen from the small intestine. No tubercle bacilli were found and no caseation. Wassermann reaction was negative.

In 1925 Frei proved the specific infective nature of certain granulomata in the rectum by his intradermal test. His antigen consisted of the filtrable virus obtained from a bubo in a known case of lymphogranuloma inguinale. Another granuloma of specific pathology was thus established, and became detached from the main non-specific group.

In 1931 Mock gave a full description of this condition, which he calls "Infective Granuloma". He considered these tumour-like masses to be influenced to a certain extent by a low-grade non-specific infection, and characterized by a piling up of granulation tissue showing varying stages of necrosis, fibroblastic changes and the true scar tissue, or reparative tissue growth. These masses, usually not well circumscribed, often reach the size of an orange, a grape-fruit, or occasionally a child's head. They are not specific granulomata. He considered the underlying cause to be some local interference with the blood supply, followed by a small area of necrosis, followed in its turn by a reparative tissue reaction. Low-grade organisms may be present at the start causing this interference with the blood supply and resulting tissue changes, or the inflammatory mass may arise first and be attacked subsequently by pyogenic organisms. He grouped the causes under three headings: (1) Conditions existing within the gastro-intestinal tract itself, or its mesentery, considering the hypertrophic mass that may develop at the site of a gastric ulcer as comparable; (2) extraperitoneal infections which gradually spread to and involve the gastro-intestinal tract, such as retroperitoneal adenitis, causing a necrotic mass; and (3) trauma, which may be produced by external injury, affecting the mesentery or intestine; partial volvulus or constriction in a hernial sac, foreign bodies or ligatures that cause interference with blood supply. The symptoms he grouped in three headings: (1) Those attributable to the inflammatory process; (2) those due to obstruction, and (3) those that are constitutional. In the treatment he advocated excision of the affected tissues, but he recognized the fact that in many cases the mass disappears after a short-circuiting operation. He stresses the importance of taking a portion of tissue for microscopic section, if the whole lesion is not to be excised.

In the following year, 1932, Crohn published his description of regional ileitis, which he considered a clinical and pathological entity that could be split off from the general mass of non-specific granulomata. He describes a disease of the terminal ileum affecting mainly young adults, characterized by a subacute or chronic necrotizing and cicatrizing inflammation. The ulceration of the mucosa is accompanied by a disproportionate connective tissue reaction of the remaining walls of the intestine, a process which frequently leads to stenosis of the lumen of the intestine, associated with the formation of multiple fistulae. The clinical features of the disease he considered to resemble most closely those of ulcerative colitis, fever, diarrhoea and emaciation, leading eventually to an obstruction of the intestine, the constant presence of a mass in the right iliac fossa usually requiring surgical intervention.

In this original description he stated the condition was limited to the terminal ileum, the process beginning at, and involving in its maximal intensity, the ileocaecal valve, tapering off gradually as it ascends the ileum for 8 to 10 in. The familiar fistulae lead usually to segments of the colon forming small tracks, communicating with the lumen of the large intestine. Occasionally the abdominal wall anteriorly is the site of one or

C. F., woman aged 23. Her symptoms were pain in the right side and diarrhoea, and a tumour in the right iliac fossa was found on examination. At operation the terminal ileum and its mesentery were found to be thickened. Resection was carried out, and the tissue showed naked-eye and microscopic appearances of Crohn's disease.

The interest in this case lies in pain and diarrhoea being the initial symptoms and a tumour being present.

F. D., woman aged 44. She stated she had been admitted to hospital in 1927, with pain in the right side of the abdomen and vomiting. The diagnosis of appendix abscess was made and the late Mr. Russell Howard operated and according to reports found a matted mass in the right iliac fossa consisting of oedematous caecum and ileum. The appendix was not seen. The wound healed by first intention. She was admitted to hospital five months later and an abdominal abscess was drained. Two years later, 1929, cholecystectomy was performed for gall-stones, and the appendix was removed. Following this operation the patient says she kept fairly well, except for occasional pains in the stomach, until 1936, when she noticed a gradually increasing frequency of micturition and attacks of diarrhoea. After eating tomatoes she noticed the soft pips in her urine. She was admitted to a nursing home and a tender hard mass was felt in the right iliac fossa. A catheter specimen of urine contained intestinal material and a barium meal showed ileocolic and ileo-vesical fistulae. At the operation a large thickened loop of ileum was found lying on the bladder, with a communication between the ileum and the bladder, in an area acutely inflamed. The ileum terminated in a mass of adherent tissues containing caecum and ileum in the right iliac fossa. The appearances were those of the then recognized Crohn's disease. The ileum was detached from the bladder, openings in ileum and bladder were closed, and omentum was sutured between the two viscera. The patient made a good recovery, got strong again and felt well after this operation, for a year. Periods of ill-health then returned with abdominal pain and frequency of micturition, with fibres in the urine.

I saw her first in February 1944, when she complained of increased frequency of micturition, and colicky abdominal pains. She was a thin, pale woman, the abdomen was distended and peristaltic waves were clearly visible. There was tenderness in the right iliac fossa but no mass could be felt. The urine contained pus cells, meat fibres and vegetable cells. It was clear that a communication existed between the ileum and the bladder, and that partial obstruction of the intestine was taking place. At the operation, I found a scarred mass in the right side of the pelvis binding down lower ileum to bladder. The ileum was dilated and numerous inflammatory patches were present in its wall. I joined ileum to ascending colon and did not disturb the mass. She made a satisfactory recovery. The urine cleared up before she left the nursing home, and there was no further abdominal discomfort. She has subsequently steadily gained weight and had no recurrence of symptoms.

The interest in this case lies in the recurrence of the ileo-vesical fistula after the careful and thorough closure, which suggests that the pathological process at work in Crohn's disease is an infective one.

Comment.—If any inference can be drawn from such a short series of personal cases it is perhaps the very varied clinical picture that these intestinal granulomata do present. In two of my cases severe haemorrhage was the chief symptom. In two of them fistula, and in one abdominal pain, and the presence of a tumour.

There is no clear pointer to the aetiology but an infective origin is suggested by the fact that the active pathological process continued after operative treatment, which probably did not completely remove the lesion.

Sir Philip Manson-Bahr: *Crohn's disease: Chronic cicatrizing enteritis: Regional ileitis.*—It is necessary to study the characteristics and implications of this disease of the small intestine, for there are reasons to believe that it may on occasions extend to the colon as well.

The credit for the first description of regional ileitis is usually accorded to Crohn. Ginzburg and Oppenheimer in 1932, though it is now pointed out that an accurate

SUMMARY

It is clear to us now that non-specific intestinal granuloma, when first recognized, constituted a mass of conditions of undetermined pathology. In the course of time lesions of determined pathology were split off the mass, such as diverticulitis and lympho-granuloma. We are left with a condition affecting mainly the ileum, and less frequently the colon, and the problem of its aetiology has not yet been completely solved.

The histological appearances and the liability to recur after operation appear to point to an infection, the true nature of which is at present unknown. In two of the cases in this short series that I am about to describe, this view appears to be supported.

CASES

This short series of cases that I have had—5 only in the past five years—are of interest in showing the different clinical pictures that the condition may present.

D. T. D., aged 49. I was first called to see him in November 1937 for a sudden severe rectal hæmorrhage, so severe as to endanger life. He subsequently regained his normal health, but some months later, another, but small hæmorrhage, took place. Sigmoidoscopy showed darkish blood coming from above the reach of the instrument. Barium enema X-ray was interpreted as showing colitis and an ulcer in the iliac colon. Laparotomy was advised, but after a further opinion, medical treatment was adopted—a period of rest in bed and a non-roughage diet. His general health was fairly good till 1940, when he had an attack of acute pain in the left iliac fossa. Examination revealed a tender mass that was thought to be a diverticulitis, or possibly colon carcinoma with peritoneal involvement. At operation in June 1940, the mass was found to be thickened descending colon. It was resected and an end-to-end anastomosis carried out, and a safety valve cæcostomy established. The pathologist's report on the tissue was Crohn's disease. The wound did not heal by first intention, and a purulent discharge persisted.

In 1942 a transverse colostomy was established, and the original wound then healed. The interest in this case was the hæmorrhage as the initial symptom. Pain and tumour were later manifestations. The persistent suppuration after the resection seems to suggest that the condition was infective and was not completely removed at operation.

S. D., man aged 49. He was admitted to hospital in March 1940 with symptoms suggesting a grumbling appendix, that had become more acute recently. There was a tender swelling in the right iliac fossa. At operation an abscess was found and an inflammatory mass involving the appendix. The appendix was removed, and the wound drained. The pathologist reported that he found no abnormality in the section of the appendix. The pus showed no tubercle bacilli and the culture yielded growth of micrococci only. The wound healed slowly but soundly. Thirteen months later he was readmitted to hospital, with pain in the right iliac fossa and a tumour, the size of an orange. An abscess was found and drained. The wound was slow in healing. Three months later the wound broke down, and a sinus formed. No specific organisms were found in the discharge. A laparotomy was performed and thickening of the terminal ileum found. Resection of the terminal ileum, cæcum and ascending colon was carried out. The wound healed well. Examination of the portion of terminal ileum removed showed the typical appearances of Crohn's disease, and this was confirmed by microscopic section.

The interest in this case lies in the mistake in the diagnosis in the first place, the recurrence of the suppuration suggesting that the early symptoms were wrongly attributed to the appendix. The initial symptoms were pain in the right side and the presence of a tumour.

M. L. M., woman aged 25. Her appendix had been removed some years previously. One year before admission she had passed a considerable amount of dark blood from the bowel on one occasion. On admission to hospital, an ill-defined mass was felt in the right iliac fossa. At operation an abscess was found beneath the abdominal wall, and in the centre of it was a piece of silkworm-gut. Some thickening of the ileum was noted, and a small portion taken for microscopic section. Cultures of the pus gave *B. coli* and no tubercle bacilli or streptococci or *Streptothrix actinomycetes*. The microscopic appearances of the tissue were suggestive of Crohn's disease. The wound healed and the patient made a good recovery. She went home and kept well for six months when a severe rectal hæmorrhage occurred and she was readmitted to hospital. Her hæmoglobin had dropped to 22%. This was restored to normal limits by giving her blood, but another hæmorrhage took place during her recovery.

A diagnosis of regional ileitis was made and a laparotomy performed. The terminal ileum was found to be thickened and a resection was carried out. The appearances of the tissue and the microscopic section confirmed the diagnosis of Crohn's disease. The foreign body, the portion of silkworm-gut, had apparently been in the tissues since the previous operation five years before and, though probably responsible for the abscess that surrounded it, could not be considered the cause of the granulomatous condition of the bowel, in the light of the histological findings.

The interest in this case lies in there having been a previous appendicectomy, in the discovery of a foreign body in the abscess, and the bleeding being the initial symptom.

Blackburn *et al.* (1939) thought that the giant cell systems were indistinguishable from those of tuberculosis. Cutler (1939, *N.Y. St. J. Med.*, 39 (i), 328) tested out his cases with Johnin, a by-product of the growth of the pseudo-tubercle bacillus of cicatrizing enteritis of cattle, but his results were negative.

(2) *Lymphogranuloma inguinale*.—The general form of the lesions in the large bowel, when these are encountered, bears a resemblance to the intestinal phenomena of lymphogranuloma as noted by Stafford (1938, *Johns Hopk. Hosp. Bull.*, 62, 399) and by James (1938, *Brit. J. Surg.*, 25, 511) who recorded a case in which the colon alone was involved. Likely and Lisa (1939, *Amer. J. Digest. Dis.*, 6, 113) found at autopsy multiple granulomata of the ileum and colon together with the genito-ano-rectal syndrome in a negress. The resemblance in this case extended to the histological appearances which in lymphogranuloma inguinale also consist of a lymphatic hyperplasia. However, Stafford (1938) tested out three of his regional ileitis cases with Frei antigen with negative results. My aim here is to point out that that form of non-specific granuloma of the colon which is treated at some length in American literature is probably identical with Crohn's disease. The term "granuloma" is applied to tumour-like inflammations of the colon not due to any demonstrable organism. There is described pericolic inflammation of low-grade type, which, whilst not causing any marked reaction in the intestine itself, yet brings about a hyperplastic reaction in the adjacent omentum until the thickening involves the wall in a tumour-like formation. The adjacent lymphatic glands become implicated. There may be, as in the ileum, mucosal ulcers.

Many of these granulomatous tumours occur in the region of the cæcum and may closely mimic a malignant tumour. Microscopically this granuloma resembles a mass of granulomatous tissue and consists of the same cellular elements, including Langhans' giant cells containing crystalline bodies (Rankin, F. W., Bergen, J. A., and Buie, L. A., 1935, "The Colon, Rectum and Anus", p. 207, Philadelphia and London).

(3) *Phlegmonous enteritis*, originally described by Rokitsansky (1842), has the same pathology as that of Crohn's disease as pointed out by Clark and Wright (1937). Its resemblance to phlegmonous gastritis has already been commented upon.

(4) *Dysentery*.—Felsen (1936) claimed from a correlated study of 553 cases that both acute and chronic ileitis might result and that this pointed to a common ætiology. He claimed to have obtained positive cultures of *B. dysenteriae*, Flexner and Sonne, during the acute stages and positive agglutination tests in the chronic. There has been no confirmation from other sources.

(5) *Sarcoidosis of Boeck*.—Williams and Nickerson first suggested that chronic ileitis might be related to sarcoidosis. With this object in view they emulsified a skin lesion from a proven case of sarcoidosis which gave positive intradermal reactions in two other cases of sarcoidosis and also in two of regional ileitis.

Sarcoidosis is identical with benign lymphogranulomatosis first described by Schaumann in 1914 (Hadfield, C., and Garrod, L. P., 1942, "Recent Advances in Pathology", p. 46, London). The histological picture (as in Crohn's disease) consists of large pale-staining cells of the endothelial type arranged in follicles resembling miliary tubercles as in some of them there is a centrally or laterally placed giant cell of the Langhans' type. I would like to suggest for future investigation that the virus which produces these lesions might be related to that of lymphogranuloma inguinale (which also gives rise to a similar cell picture). The difficulty surely consists in isolating this virus from intestinal and contaminated lesions. Ravant, Levaditi, Lambling, and Cachera (1932, *Bull. Acad. Méd., Paris*, 107, 3, 97) overcame this successfully in the case of lymphogranuloma inguinale by inserting a portion of the rectal stricture under the skin of guinea-pigs, subsequently dissecting out the enlarged lymphatic glands which contained the virus in a pure state, making an emulsion of them, and injecting this intracerebrally into white mice and monkeys, thus producing the typical encephalitis. In this manner the virus was isolated and transmitted in a pure state.

(6) *Lymphatic obstruction*.—Reichert and Mathes (1936), by injecting various sclerosing agents into the mesenteries and subserosal lymphatic channels and at the same time introducing bacteria intravenously, were able to produce œdema and extensive infiltration of the bowel wall. They concluded that regional ileitis was none other than a low-grade lymphatic infection, but Barrington-Ward and Norrish (1938, *Brit. J. Surg.*, 25, 530) suggested that disease of the mesenteric glands might be primary and that the ileitis might be due to the lymphatic block.

(7) *Infection through the mucosa*.—Although attempts have been made to identify organisms by aerobic and anaerobic cultures there are few reports of successful results,

account was given at the beginning of the last century by Combe and Saunders before the Royal College of Physicians, London, under the title of: "A singular case of stricture and thickening of the ileum."

Since 1932 a great literature has been built up around this disease. Approximately 160 papers dealing with this condition are listed in the *Cumulative Index* during the years 1939-1943. Shapiro, reviewing the literature in August 1939, tabulated 519 cases of regional ileitis in whom operative measures had been carried out (*Amer. J. med. Sci.*, 1938, 269).

Regional ileitis usually and mainly affects the terminal portions of the ileum; it sometimes also extends to the jejunum and ileocecal region. There is some evidence that circumscribed granulomata (so far known as non-specific granuloma) in the colon are of the same nature, as will be detailed later.

The regional lymphatic glands are enlarged and there is also thickening of the mesentery. Up to 1934 almost all recorded cases were to be found in the American literature, but since then there have been numerous references in English medical journals. The disease is more common in males and in Crohn's original series there were more than twice as many males as females. Originally described as affecting chiefly young adolescents, cases have been reported involving all ages.

The best and most recent account of the pathology is by A. Lyall (1945, *Glasgow med. J.*, 25, 1).

Pathology.—Two or more areas of the bowel may be rarely involved. The lengths of uninvolved bowel separating these areas are often called "skip areas". Blackburn and his co-workers (1939, *Bart's Hosp. Rep.*, 72, 181) speak of a "specific response" which they observed in 13 out of 20 cases. They noted marked hyperplasia of the lymphadenoid tissue in the submucosa producing cellular masses measuring 3 mm. in diameter; in some of these follicles the so-called "specific response" was seen and the germinal centres were replaced by proliferating endothelial cells. A basic problem which arises in the study of the pathology is whether this condition is chronic like tuberculosis or whether the early stages correspond to those of phlegmonous gastritis to which it bears some resemblance. As will be readily realized emphasis is laid on the histology as suggesting the identity of these various lesions.

The pathology can be divided into various stages:

(a) *Stage of acute suppuration.*—The affected length of the bowel is dark red in colour, greatly thickened and there are usually yellow shreds of fibrin adherent to the inner mucosa. The near-by glands are enlarged and red in colour. There is free, sometimes turbid, fluid in the peritoneal cavity. Miliary abscesses sometimes found in the submucosa resemble those seen in full-blown phlegmonous gastritis.

(b) *Chronic stage.*—Descriptions of this stage are commonly found in the literature. The naked-eye appearance of the affected bowel is typical and corresponds to Dalziel's simile of "an eel in a state of rigor mortis" or more commonly referred to as the "hose-pipe appearance". The serous surface of the bowel has a greyish-pink colour with white thickened patches representing organized fibrin. The terminal portions of the affected loop are often affixed to the pelvic brim by recent adhesions.

(c) *The fibro-stenotic stage.*—In this the cellular structure has been largely replaced by fibroblasts which have laid down collagen fibres and these have produced marked narrowing of the area. It is this stenosis which gives rise to the radiographic "string sign of Kantor". As this constriction advances the blood and lymphatic supplies of the bowel become interfered with and widespread ulceration of the mucosa takes place.

(d) *Fistula formation.*—As originally pointed out by Crohn there is a marked tendency to the formation of fistula and this may precede even the initial symptoms. These fistulae sometimes travel a long distance before reaching the surface. It has been suggested that they may be of chemical origin due to the action of the intestinal juices or possibly to the virus of lymphogranuloma inguinale.

Ætiology.—(1) *Tuberculosis.*—The chronic stages of Crohn's disease have certain resemblances to tuberculosis of the hyperplastic type, but no subserous tubercles have ever been demonstrated. That the disease is progressive like that of tuberculosis is seen by the fact that in some cases in which resection of the ileocecal portion has been performed the disease has subsequently reappeared in the ileum. Every effort made by different investigators to demonstrate tubercle bacilli, mainly by injection of material into guinea-pigs, has signally failed.

Blackburn *et al.* (1939) thought that the giant cell systems were indistinguishable from those of tuberculosis. Cutler (1939, *N.Y. St. J. Med.*, 39 (i), 328) tested out his cases with Johnin, a by-product of the growth of the pseudo-tubercle bacillus of cicatrizing enteritis of cattle, but his results were negative.

(2) *Lymphogranuloma inguinale*.—The general form of the lesions in the large bowel, when these are encountered, bears a resemblance to the intestinal phenomena of lymphogranuloma as noted by Stafford (1938, *Johns Hopk. Hosp. Bull.*, 62, 399) and by James (1938, *Brit. J. Surg.* 25, 511) who recorded a case in which the colon alone was involved. Likely and Lisa (1939, *Amer. J. Digest. Dis.*, 6, 113) found at autopsy multiple granulomata of the ileum and colon together with the genito-ano-rectal syndrome in a negress. The resemblance in this case extended to the histological appearances which in lymphogranuloma inguinale also consist of a lymphatic hyperplasia. However, Stafford (1938) tested out three of his regional ileitis cases with Frei antigen with negative results. My aim here is to point out that that form of non-specific granuloma of the colon which is treated at some length in American literature is probably identical with Crohn's disease. The term "granuloma" is applied to tumour-like inflammations of the colon not due to any demonstrable organism. There is described pericolic inflammation of low-grade type, which, whilst not causing any marked reaction in the intestine itself, yet brings about a hyperplastic reaction in the adjacent omentum until the thickening involves the wall in a tumour-like formation. The adjacent lymphatic glands become implicated. There may be, as in the ileum, mucosal ulcers.

Many of these granulomatous tumours occur in the region of the cæcum and may closely mimic a malignant tumour. Microscopically this granuloma resembles a mass of granulomatous tissue and consists of the same cellular elements, including Langhans' giant cells containing crystalline bodies (Rankin, F. W., Barga, J. A., and Buie, L. A., 1935, "The Colon, Rectum and Anus", p. 207, Philadelphia and London).

(3) *Phlegmonous enteritis*, originally described by Rokitsansky (1842), has the same pathology as that of Crohn's disease as pointed out by Clark and Wright (1937). Its resemblance to phlegmonous gastritis has already been commented upon.

(4) *Dysentery*.—Felsen (1936) claimed from a correlated study of 553 cases that both acute and chronic ileitis might result and that this pointed to a common ætiology. He claimed to have obtained positive cultures of *B. dysenteriæ*, Flexner and Sonne, during the acute stages and positive agglutination tests in the chronic. There has been no confirmation from other sources.

(5) *Sarcoidosis of Boeck*.—Williams and Nickerson first suggested that chronic ileitis might be related to sarcoidosis. With this object in view they emulsified a skin lesion from a proven case of sarcoidosis which gave positive intradermal reactions in two other cases of sarcoidosis and also in two of regional ileitis.

Sarcoidosis is identical with benign lymphogranulomatosis first described by Schaumann in 1914 (Hadfield, G., and Garrod, L. P., 1942, "Recent Advances in Pathology", p. 46, London). The histological picture (as in Crohn's disease) consists of large pale-staining cells of the endothelial type arranged in follicles resembling miliary tubercles as in some of them there is a centrally or laterally placed giant cell of the Langhans' type. I would like to suggest for future investigation that the virus which produces these lesions might be related to that of lymphogranuloma inguinale (which also gives rise to a similar cell picture). The difficulty surely consists in isolating this virus from intestinal and contaminated lesions. Ravant, Levaditi, Lambling, and Cachera (1932, *Bull. Acad. President—Professor NORMAN B. CAPON, M.D.

[November 23, 1945]

Pulmonary Haemosiderosis.—A. D. BARLOW, M.B., M.R.C.P. (for Dr. DONALD PATERSON).

E. B., female, aged 6 years 10 months. Born 2.1.39.

Family history.—Mother alive and well. Father died of coronary thrombosis. Only child.*History.*—Normal birth; birth-weight 6 lb. 8 oz. Artificially fed. Born in Germany. Father German, mother Jewess.

Came to England at 8 months. Good health until 18 months, when she had a severe attack of bronchitis requiring admission to hospital. A chest X-ray had the appearance of military tuberculosis. At the age of 2 years attacks of breathlessness occurred every few weeks, diagnosed as asthma. At 3 years these attacks became less severe, being very mild at 3 years 6 months. An attack was characterized by severe cough and dyspnoea, but there was no sputum.

From 3½ years old she has always been very pale, her Hb. ranging from 30% to 70%. In December 1944 (aged 5½) and again in February 1945 she required blood transfusions.

Since January 1945 she has received liver injections (Examen 1 c.c. two to three times a week), iron and vitamin B (Benerva compound), but her Hb. has always remained below 70%.

In September 1945 she became rapidly more anæmic, and on 19.9.45 she was admitted to Great Ormond Street Hospital.

On admission.—She was very pale; weight 34 lb., nutrition poor. Liver 1 in. below costal margin. Spleen just palpable. Tonsillar glands enlarged, but no generalized glandular enlargement.

R.E.C.	2,800,000	White cells	8,600
Hb.	30% (4.2 grammes)	Lymphocytes	30%
C.I	0.55	Polymorphs:	
Reticulocytes	1.6%	Segmented	46%
No spherocytosis.		Stab	20%
Erythrocyte fragility normal.		Eosinophils	4%

Chest X-ray: A fine mottled appearance spreads almost to the periphery.

She was transfused, but during the following three weeks her red blood-count fell from 5.1 to 3.1 millions.

There was no evidence of bleeding: Occult blood negative; urine normal; no hæmoptysis at that time.

25.9.45.—Sternal puncture showed normal bone-marrow.

Total nucleated cell-count 86,000 per c.mm.

Hæmocyto blasts	0	Blast cells	0
Primary erythroblasts	1.5%	Myelocytes:	
Late erythroblasts	2%	Neutrophil	13%
Normoblasts	24%	Eosinophil	1%
		Metamyelocytes (neutrophil)	2%
		Polymorphs:	
		Segmented	7%
		Stab	34%
		Eosinophils	1.5%
Undifferentiated cells	0.25%	Lymphocytes:	
Mitotic cells	0.25%	Large	0.5%
		Small	13%

Leuko-erythroblastic ratio 2.7 : 1

Reticulocytes 5% (in peripheral blood)

Serum bilirubin 2.1 mg. per 100 c.c.

The evidence points to a hæmolytic process but not acholuric jaundice, as the fragility was normal, and no spherocytes were seen.

Mixer (1935, *Ann. Surg.*, 102, 674) and Jackman (1934, *Brit. J. Surg.*, 22, 27) indeed isolated a streptococcus of the enterogenous type from the floor of the ulcers as well as from the peritoneal fluid.

If the bacterial nature of the disease is accepted we must also be prepared to explain the mode of entry of the infection. The ulceration might well prove the site of entry of the primary infection. Ralphs suggested that an important part might be played by trauma such as fish bones.

Histology.—The best account of the histology is that of Hadfield, G. (1939, *Lancet* (ii), 775). This remains at present the only safe means of identifying the lesion and is, in fact, the result of hyperplasia of the lympho-reticular tissue leading to obstructive lymphœdema. The lymphadenoid masses vary in size, the largest forming cellular aggregates 3-4 mm. in diameter, visible to the naked eye. The smallest are 0.4 mm. in diameter and microscopic in size. In three-quarters of the cases these cellular nodes are scattered evenly through the œdematous mucosa, being 8-18 to the square centimetre. They show considerable cellular activity, a characteristic cellular response in a variable number of germinal centres making up a nodule of lymphadenoid tissue. The affected germinal centre is later replaced by proliferating endothelial cells with weakly staining nuclei.

In the midst of the cells constituting endothelial aggregates it is usually possible to find a Langhans' giant cell which, when mature, resembles the giant-cell system of miliary tuberculosis, but when this system has reached its full development all proliferation apparently ceases.

Never has the slightest evidence of caseation been seen. Some of the cells contain crystalline masses of various shapes and sizes. Probably the most arresting histological feature is the presence in the regional lymph nodes of a clear-cut specific formation of giant-cell systems identical with that of the thickened mucosa. The natural retrogression of this lesion can best be studied in this situation.

When viewed as an isolated and static histological picture the giant-cell systems, both in the glands and the bowel, are indistinguishable from those of tuberculosis, but the absence of caseation and of acid-fast bacilli force one to doubt its tubercular origin.

From the purely histological aspect, the appearance, evolution and retrogression, the giant-cell system of Crohn's disease more resembles the tissue reaction of Boeck's sarcoidosis than of tubercle infection.

[November 23, 1945]

Pulmonary Hæmosiderosis.—A. D. BARLOW, M.B., M.R.C.P. (for Dr. DONALD PATERSON).

E. B., female, aged 6 years 10 months. Born 2.1.39.

Family history.—Mother alive and well. Father died of coronary thrombosis. Only child.

History.—Normal birth; birth-weight 6 lb. 8 oz. Artificially fed. Born in Germany. Father German, mother Jewess.

Came to England at 8 months. Good health until 18 months, when she had a severe attack of bronchitis requiring admission to hospital. A chest X-ray had the appearance of milary tuberculosis. At the age of 2 years attacks of breathlessness occurred every few weeks, diagnosed as asthma. At 3 years these attacks became less severe, being very mild at 3 years 6 months. An attack was characterized by severe cough and dyspnoea, but there was no sputum.

From 3½ years old she has always been very pale, her Hb. ranging from 30% to 70%. In December 1944 (aged 5½) and again in February 1945 she required blood transfusions.

Since January 1945 she has received liver injections (Examen 1 c.c. two to three times a week), iron and vitamin B (Benerva compound), but her Hb. has always remained below 70%.

In September 1945 she became rapidly more anæmic, and on 19.9.45 she was admitted to Great Ormond Street Hospital.

On admission.—She was very pale; weight 34 lb., nutrition poor. Liver 1 in. below costal margin. Spleen just palpable. Tonsillar glands enlarged, but no generalized glandular enlargement.

R.E.C.	2,800,000	White cells	8,600
Hb.	30% (4.2 grammes)	Lymphocytes	30%
C.I.	0.55	Polymorphs:	
Reticulocytes	1.6%	Segmented	46%
No spherocytosis.		Stab	20%
Erythrocyte fragility normal.		Eosinophils	4%

Chest X-ray: A fine mottled appearance spreads almost to the periphery.

She was transfused, but during the following three weeks her red blood-count fell from 5.1 to 3.1 millions.

There was no evidence of bleeding: Occult blood negative: urine normal; no hæmoptysis at that time.

25.9.45.—Sternal puncture showed normal bone-marrow.

Total nucleated cell-count 86,000 per c.mm.

Hæmocytoblasts	0	Blast cells	0
Primary erythroblasts	1.5%	Myelocytes:	
Late erythroblasts	2%	Neutrophil	13%
Normoblasts	24%	Eosinophil	1%
		Metamyelocytes (neutrophil)	2%
		Polymorphs:	
		Segmented	7%
		Stab	34%
		Eosinophils	1.5%
Undifferentiated cells	0.25%	Lymphocytes:	
Mitotic cells	0.25%	Large	0.5%
		Small	13%

Leuko-erythroblastic ratio 2.7 : 1

Reticulocytes 5% (in peripheral blood)

Serum bilirubin 2.1 mg. per 100 c.c.

The evidence points to a hæmolytic process but not acholuric jaundice, as the fragility was normal, and no spherocytes were seen.

In view of the uniformly bad prognosis of the cases previously published, and in the hope that it might be possible to avert further hæmolytic episodes, her spleen was removed (by Mr. Charles Donald) on 19.10.45. However, the blood-count has again fallen since the operation, and once more there is evidence that a hæmolytic process is responsible.

Reticulocytes 10%, serum bilirubin 1.9 mg., urobilin in urine greater than normal.

Comment.—The evidence in favour of this being a case of pulmonary hæmosiderosis is: (1) The chest X-ray, persistent for five years; (2) the refractory anæmia; (3) biopsy of her lung, by aspiration (performed elsewhere), showed numerous hæmosiderin-filled macrophages; (4) a history of hæmoptysis.

Since discharge this child has had two small hæmoptyses.

Refractory Anæmia.—A. D. BARLOW, M.B., M.R.C.P. (for Dr. DONALD PATERSON).

E. J. B., female. Normal birth (28.3.45). Weight 10 lb. 6 oz. No neonatal jaundice.

Family history.—Parents alive and well. Brother and sister normal (no neonatal jaundice or anæmia).

History.—Pallor gradually increased since birth, at 3 months her hæmoglobin was 24%. She was transfused, but three weeks later was again anæmic, the Hb. being 49%. Transfusion has been necessary every three to five weeks since then, six times in all. At 3 months old she passed bright red blood with her motions on one occasion, but has not had macroscopic blood since then. A purulent discharge from her right ear was noticed at 4 months.

Clinical findings.—Admitted to Great Ormond Street Hospital 29.9.45 aged 6 months. Well-nourished rather fat baby, weight 16 lb. Very pale, slight icteric tint to sclerotics. Liver 1 in., spleen 1½ in. below costal margin. Right ear discharging. Otherwise no abnormal findings, no general glandular enlargement.

Investigations.

30.9.45.—Blood-count:

R.B.C.	1,330,000	White cells	17,700 per c.mm.
Hb.	30% (4.2 grammes)	Lymphocytes	54%
C.I.	1.1	Polymorphs:	
Reticulocytes	0.2%	Segmented	10%
M.C.D.	7.1 μ	Stab	34%
Normoblasts	2 per 100 white cells	Eosinophils	2%
Hæmogram	9.11.45 (thirty-eight days after 500 c.c. Rh negative blood):		
R.B.C.	2,210,000	W.B.C.	10,500
Hb.	50% Sahli (7 grammes)	Polymorphs:	
C.I.	1.13	Segmented	15%
		Stab	13%
Normoblasts	2 per 100 W.B.C.	Eosinophils	2%
		Lymphocytes	69%
Slight anisocytosis and poikilocytosis		Monocytes	1%
No polychromasia			
		Platelets	350,000 per c.mm.
Reticulocytes	0.2%		
Packed cell vol.	20 c.c. per 100 c.c. (normal 42 c.c. per 100 c.c.)		
Mean corpuscular vol.	91 μ^3 (78 - 94 μ^3)		
Volume index	1.08 (0.85 - 1.15)		
Mean corpuscular Hb. concentration	35.5% (32 - 38%)		
Mean corpuscular diameter	7.1 μ		
B.S.R. (Wintrobe):			
Uncorrected	68 mm. per hour.		
Corrected for anæmia	19 mm. per hour.		
Red cell fragility	within normal limits.		

Bone-marrow (14.11.45) from tibia—400 cells counted.

Hæmocytoblasts	0	Leukoblasts	0.25%
Primary erythroblasts	1%	Myelocytes:	
Late erythroblasts	2.5%	Neutrophil	1%
Polychromatic normoblasts	10%	Eosinophil	0.25%
Hæmoglobinized normoblasts	7%	Metamyelocytes:	
		Neutrophil	1.75%
Large lymphocytes	2%	Eosinophil	0.25%
Small lymphocytes	53%	Polymorphs:	
		Neutrophil	9%
Mitotic cells	0.5%	Eosinophil	1%
Megakaryocytes	0.5%	Stab forms	10%

Leuko-erythroblastic ratio = 4:1

Total nucleated cells 37,000 per c.mm.

Mother group 0 Rh positive.

Baby group 0 Rh positive.

Baby's blood contains cold agglutinins in titre 1:4. W.R. and Kahn negative.

Blood cholesterol 95 mg. per 100 c.c.

Fractional test meal (histamine): Hypochlorhydria.

X-rays of chest, skull and long bones show no abnormality.

Progress.—Transfusion raised her red count to 4.86 millions; 100% Hb. But during the ensuing five weeks it gradually sank to 2.2 millions with 50% Hb. (7 grammes), resisting numerous forms of therapy.

The cause of her anæmia remains obscure: but amongst the possibilities which might be considered are:

Hæmorrhage: There was hæmorrhage from the bowel on one occasion, at 3 months. While in hospital her anæmia has increased steadily without any evidence of bleeding (the occult blood was weakly positive once, but repeatedly negative at other times).

Hæmolysis: Her serum bilirubin has been 2.5 mg. per 100 c.c., which may indicate increased hæmolysis (liver function, phosphatase and Takata-Ara tests normal), alternatively it may represent a defect in utilizing the products of normal erythrocyte destruction.

Diminished erythropoiesis: The persistently low reticulocyte count, the low total count of nucleated cells in the bone-marrow (37,000) with leuko-erythroblastic ratio of 4:1, considered in relation to the degree of anæmia (2.2 millions), would seem to indicate a low rate of formation of red cells.

Depression of the marrow by infection seems to be excluded by lack of improvement following mastoidectomy (no other focus of sepsis than her ear could be found).

She has not responded to large doses of iron (15 grains per day) by mouth, nor to liver by mouth or injection, nor to vitamin-B complex injections.

Nephrocalcinosis associated with Hyperchloræmia.—W. W. PAYNE, M.B., M.R.C.P.

G. F., female, aged 10½ years.

History.—Apparently normal till 1 year 8 months. Then "kidney trouble" for two years. Has had measles, scarlet fever, diphtheria and tonsillectomy. No relevant family history.

On examination.—Small, thin, intelligent child with knock knees. Good appetite. Polyuria. Height 43 in. Weight 43½ lb.

Investigations.—Urine alkaline, Sp.gr. 1006. Albumin 55 mg. per 100 c.c. Deposit: "Addis count" R.B.C. 8,000,000 per day. W.B.C. 220,000,000 per day. No casts or crystals. Urea concentration test: 9 a.m. 198 c.c. urea 0.81%; 10 a.m. 103 c.c. urea 1.20%; 11 a.m. 98 c.c. urea 1.25%; 12 noon 73 c.c. urea 1.24%.

X-ray (Dr. L. B. Blair): Multiple deposits of calcium density in both kidneys. Bones show some thinning of the cortex. No other abnormality.

Blood Investigations.

Hb. 75%, W.B.C. 8,900 per c.mm. (polys 36%; lymphos: large 4%, small 58%; eosinos. 2%).

	Before treatment	After treatment	Normal
Urea	22	27	20-35 mg. per 100 c.c.
Inorganic phosphorus	3.1	4.1	4-5.5 mg. per 100 c.c.
Calcium	10.2	-	9-11 mg. per 100 c.c.
Chlorides (as NaCl)	677	655	560-630 mg. per 100 c.c.
Bicarbonate	37	49	49-63 vols. CO ₂
Phosphatase	30.6	14	5-15 units
Cholesterol	169	-	100-200 mg. per 100 c.c.

Treatment (Albright *et al.*) 60 c.c. daily of the following solution: citric acid 140 grammes, sodium citrate 98 grammes, water to 1,000 ml. Also 30,000 units daily of vit. D.

This case resembles the cases described by Albright *et al.* [1], Baines *et al.* [2] and Rule and Grollman [3]. The cause is obscure.

My thanks are due to Dr. D. Paterson for permission to report this case.

Two Cases of Banti's Syndrome: Hepatomegaly with Anæmia.—CHARLES PINCKNEY, F.R.C.P.

Two children of the same family, R. P. and K. P.

(1) R. P., female, aged 8. Admitted July 1944 with hæmatemesis.

Blood-count.—Before transfusion: R.B.C. 2,340,000; Hb. 39%; C.I. 0.8. W.B.C. 1,400 per c.mm. Leucocytes normal in appearance. Red cells: anisocytosis and polychromasia. Volume of packed cells: 19%. Mean corpuscular vol. 81 cu. μ . M.C. Hb. conc. 28%. M.C. diameter 7.6 μ , average thickness 1.8 μ . E.S.R. 20 mm. in one hour. Reticulocytes 8%.

After transfusion: Hb. 50%.

Given intravenous blood transfusion, 1 pint. Fragility curve normal. W.R. and Kahn negative. Serum bilirubin 0.4 mg. %, phosphatase 11 units, and colloidal gold reaction, weakly positive (1+). Urine—bile salts, urobilin, urobilinogen, bilirubin not detected. Sternal puncture—moderately active marrow with no significant changes. Stercobilin within normal limits. Galactose tolerance test—galactose index = 65 (normal).

(Mother's blood normal. W.R. and Kahn negative.)

Discharged with Hb. 83%.

Readmitted December 1944 with further hæmatemesis. Hb. 55%. Given further intravenous blood transfusion. Discharged with Hb. 72%.

Readmitted July 1945 with acute nephritis following acute tonsillitis. Made a good recovery in six weeks.

Liver function tests: Serum bilirubin 0.4 mg. per 100 ml. Thymol test 3 units. Serum colloidal gold weakly positive (1+). Urine urobilin negative.

Clinical examination shows liver enlarged three fingerbreadths below costal margin, hard, irregular, not tender. Spleen not enlarged.

(2) K. P., aged 3 years.

3.10.44: R.B.C. 4.65 millions; Hb. 84%; C.I. 0.9. W.B.C. 13,450 (polys. 59%, lymphos. 30%, monos. 11%). Red cells normal.

31.10.44: R.B.C. 4.96 millions; Hb. 87%; C.I. 0.90.

5.12.44: R.B.C. 4.89 millions; Hb. 86%; C.I. 0.89. W.B.C. 10,800 (polys. 24%, lymphos. 70%, monos. 3%, eosinos. 3%).

1.6.45: R.B.C. 5.37 millions; Hb. 96%; C.I. 0.9.

Clinical examination.—Abdomen: Liver enlarged three to four fingerbreadths below costal margin, hard, irregular and not tender. Spleen not enlarged.

Collapsed Intervertebral Discs following Lumbar Puncture.—URSULA JAMES, M.B., M.R.C.P.

Brian C., aged 4½ years, underwent lumbar puncture in January 1945 during investigation of recent fits. Fluid, which was withdrawn only after several attempts, was normal. No further fits.

One week later admitted to hospital. T. 104°F. Had been listless for three days, walking cautiously, hips flexed, supporting himself with hands above knees. He had been screaming at night and had vomited twice. He resented examination, especially flexion of hips, and sat up with difficulty. Lumbar spine rigid, loss of lordosis. He awakened frequently from sleep screaming with pain. C.S.F. normal. W.B.C. 15,150 (polys. 87.5%). Mantoux 1:1,000 and 1:100 negative. X-ray of spine normal.

Temperature settled for a few days then started to swing—child developed chicken-pox. Nine days later X-ray of spine showed narrowing of intervertebral space between L3 and L4. Narrowing increased and space L4 to L5 became affected. Four weeks later there was erosion of upper surface of fourth lumbar vertebra and sclerosis surrounded it.

After the first positive X-ray the child was put into a plaster bed in moderate extension. Penicillin was given for six days (50,000 units daily) because at this time it was thought that the lesion might be a low-grade osteomyelitis. The temperature fell and the general condition improved slowly.

He was kept in a plaster bed for four months, then walked about in a plaster jacket for two months. He was then and is still free from symptoms.

Two Cases of Ehlers-Danlos Syndrome.—F. L. KING-LEWIS, M.R.C.S., L.R.C.P., D.C.H.

(1) T. M., boy aged $3\frac{1}{2}$ years. Weight $27\frac{1}{4}$ lb.

History.—"When he falls, he does not cut himself, he just tears open." Bruises very easily.

Signs.—Looseness and over-elasticity of skin. Hyperextensibility of joints, especially fingers. Numerous scars, forehead, legs, &c. Scars have a papyraceous, "cigarette-paper" appearance and light violet colouring. Small pseudo-tumours of connective tissue in some of the scars. Facial appearance shows exaggeration of the inner canthus.

Investigations.—W.R. negative. Bleeding time five and a half minutes. Clotting time four minutes. Platelet count 250,000 per c.mm. Capillary resistance test normal. X-ray of tooth buds appears normal.

Family history.—No other cases known of congenital loose skin or hyper-extensible joints in the family. No consanguinity of parents.

(2) R. C., girl aged 9 years. Weight $51\frac{1}{2}$ lb.

History.—Cuts herself and bruises very easily.

Signs.—Looseness and hyperelasticity of skin, mainly over knees and elbow-joints. Hyperextensibility of joints. Can touch the back of her head with her heels. Scars, especially left knee and elbows, violet, "cigarette-paper" or papyraceous atrophic scars. Fatty nodule on left thumb and in scars on knee. Scars on knee completely anæsthetic. On 4.75×2 sq. in. of skin were resected and seven stitches inserted without any pain being experienced. Facial appearance shows some increase of the inner canthus.

Investigations.—Bleeding time four and a half minutes. Clotting time three minutes. Platelets normal. Capillary resistance test normal.

Family history.—Nothing relevant.

Trigeminal Nævus and Homolateral Intracranial Angioma associated with Hypertelorism.

—R. W. B. ELLIS, O.B.E., M.D.

John R., a boy aged 3 years 3 months, was born at full term by difficult breech delivery requiring forceps. He was said to have had a "fractured skull" following delivery. He is an only child and the parents are well and unrelated. The father has been examined and shows a mild degree of hypertelorism, and judging by photographs, one brother and one sister of the father are more markedly affected. No familial history of mental defect.

Convulsions first occurred at the age of 6 weeks, and epileptiform attacks have continued since that time. The child has been free for two to three months at a time, but whilst he has been under observation at Guy's Hospital (since June 1945) the fits have been frequent and entirely uncontrolled by drugs (luminal, sodium nitrate, bromides, epanutin). He has twice been admitted to hospital and found to have frequent auricular extrasystoles, pulsus bigeminus having been observed repeatedly. During his present admission (November 10 to 21, 1945) he has had twelve fits, each of short duration (one to one and a half minutes) and preceded by an aura. The attacks which have been observed usually start with throwing out of the left arm followed by upward deviation of the eyes, twitching of the right side of the face, and kicking or flexion of the right leg. (The mother, however, states that the left side is usually most affected.) It is doubtful if he actually loses consciousness in every attack. Recovery is very rapid, after which he complains of headache and usually wishes to pass urine. There has been no incontinence during the attack. On each occasion the pulse has been noted as being "slow and irregular", "missing beats", or pulsus bigeminus has been observed.

There has been no mental deterioration.

Physical examination.—Normal physical and mental development for age. There is a faint but well-defined facial nævus covering the greater part of the area of distribution of the ophthalmic division of the fifth nerve on the left. There is a moderate degree of hypertelorism, and facial asymmetry, with facial hypotrophy on the right. Eye movements normal. Discs and fundi normal. Between the attacks the limbs show normal tone and movement; the tendon reflexes are present and equal. Plantar reflexes flexor. No ataxia or nystagmus.

The area of cardiac dullness and the heart sounds are normal, but frequent extrasystoles or continued pulsus bigeminus are usually present.

Mantoux test (1:1,000) negative.

Lumbar puncture (15.11.45): Normal cerebrospinal fluid under normal pressure. W.R. and Lange negative.

Radiological report (Dr. T. Hills).—Skull: There is some asymmetry of the lesser wings of the sphenoid, but no evidence of fracture. There are a few small calcified areas on the left side, probably anterior to the central sulcus and situated rather deeply. Some irregularity of the floor of the sella.

Comment.—The association of a facial naevus, homolateral intracranial calcification, and epilepsy appears to justify the diagnosis of an intracranial angioma, although the history of birth injury introduces a confusing factor. The epilepsy in this case is not clearly focal, but it is probably significant that twitching of the right side only of the face has been observed in several attacks. There is also hypotrophy of the right side of the face. This contralateral hypotrophy has been described by Parkes Weber (1922)

Trigeminal naevus (left frontal region) with right-sided hypotrophy of face and hypertelorism.

in a patient also showing a left-sided intracranial lesion of this type, but here there was also a congenital spastic hemiplegia on the right. The naevus in the child shown is fainter than those in many of the published cases, but conforms to the almost invariable distribution, i.e. involving the greater part of the area of distribution of the ophthalmic division of the fifth nerve. It is exceptional to find calcification appearing at the site of the intracranial angioma at such an early age. In two cases of the same type (Ellis, 1931-2), no calcification was seen radiologically in the younger boy aged 1 year 9 months, whilst the older boy, aged 9 years, showed the classical "festooned" appearance (Parkes Weber—Dimitri's syndrome) within the skull. In all three cases the epilepsy proved completely resistant to medical treatment; in the eldest boy there was some mental retardation.

In this case, the association of hypertelorism is probably fortuitous. Hypertelorism is a heredo-familial condition, and although it has only been possible to examine the father it is almost certain (from the description and photographs) that one sister and one brother of the father are also affected. As in the family described by Abernethy (1927), there is no family history of associated mental defect.

President—G. W. B. JAMES, C.B.E., M.C., M.D., D.P.M.

[November 13, 1945]

DISCUSSION: FORWARD PSYCHIATRY IN THE ARMY

Lieut.-Colonel Harold Palmer, R.A.M.C., opened the discussion by referring briefly to the history of the development of forward psychiatry. In France, prior to the Dunkirk campaign, he had been called upon to solve problems of storage psychiatry. From Dunkirk to El Alamein he had been associated with the development of methods of dealing with sick individuals. In Tripoli in 1943, the forward medical authorities of the 8th Army were persuaded to jettison the whole concept of psychiatric hospital treatment, to establish in its place a filtration centre serving three grades of rehabilitation centre and to initiate an "on the spot" system of re-allocation. In principle this meant dealing with the whole problem of the psychiatric and neurotic casualty as a problem of social medicine; as a result of this the whole set-up had only required 100 beds and two psychiatrists for an Army of 200,000 men, and was successful in returning 98% of the men to full duty. As far as possible these principles had been applied in Italy, but for one reason or another required modification, but the concept of the rehabilitation centre was carried on later in the U.K. in relation to many of the Normandy casualties.

In general, he felt that the chief lesson of his war experiences, as applied to civilian life, was the urgent and imperative need for creating filtration and rehabilitation centres in this country. In the sphere of treatment, narcosis and abreaction techniques have established themselves securely, but he felt that the latter would require patient evaluation in expert hands, otherwise it would fall into disrepute. The value of mechanized set-ups was not to be disregarded, and had their value in safeguarding the individual psychiatrist from fatigue. In particular he considered an insulin unit should always be available when handling psychotics, and he felt that the failure of many civilian authorities to provide such facilities was deplorable.

He suggested that the psychiatric problem would in all circumstances be found to be capable of analysis into six separate processes: Collection; filtration; treatment; rehabilitation; re-allocation; disposal; and he pointed out the dangers of assuming that all psychiatrists were equally equipped by experience or temperament to perform all these tasks with success.

Major C. Kenton, R.A.M.C.: Forward psychiatry in the Army includes in its scope the consideration of, and the methods of dealing with, the problems affecting the mental health and morale of troops that are exposed, by reason of geographical propinquity, to actual, or closely threatened, enemy action. This view brings into focus the prophylactic as well as the therapeutic aspects of the subject while, at the same time, it limits consideration to the problems of soldiers fighting in an ill-defined and fluctuating, but nevertheless recognizable, area of military operations. Rarely elsewhere in the Army have group loyalties and group sanctions operated so intensely, or so profoundly, affected the military psychiatric outlook.

Lumbar puncture (15.11.45): Normal cerebrospinal fluid under normal pressure. W.R. and Lange negative.

Radiological report (Dr. T. Hills).—Skull: There is some asymmetry of the lesser wings of the sphenoid, but no evidence of fracture. There are a few small calcified areas on the left side, probably anterior to the central sulcus and situated rather deeply. Some irregularity of the floor of the sella.

Comment.—The association of a facial naevus, homolateral intracranial calcification, and epilepsy appears to justify the diagnosis of an intracranial angioma, although the history of birth injury introduces a confusing factor. The epilepsy in this case is not clearly focal, but it is probably significant that twitching of the right side only of the face has been observed in several attacks. There is also hypotrophy of the right side of the face. This contralateral hypotrophy has been described by Parkes Weber (1922)

Trigeminal naevus (left frontal region) with right-sided hypotrophy of face and hypertelorism.

President—G. W. B. JAMES, C.B.E., M.C., M.D., D.P.M.

[November 13, 1945]

DISCUSSION: FORWARD PSYCHIATRY IN THE ARMY

Lieut.-Colonel Harold Palmer, R.A.M.C., opened the discussion by referring briefly to the history of the development of forward psychiatry. In France, prior to the Dunkirk campaign, he had been called upon to solve problems of storage psychiatry. From Dunkirk to El Alamein he had been associated with the development of methods of dealing with sick individuals. In Tripoli in 1943, the forward medical authorities of the 8th Army were persuaded to jettison the whole concept of psychiatric hospital treatment, to establish in its place a filtration centre serving three grades of rehabilitation centre and to initiate an "on the spot" system of re-allocation. In principle this meant dealing with the whole problem of the psychiatric and neurotic casualty as a problem of social medicine; as a result of this the whole set-up had only required 100 beds and two psychiatrists for an Army of 200,000 men, and was successful in returning 98% of the men to full duty. As far as possible these principles had been applied in Italy, but for one reason or another required modification, but the concept of the rehabilitation centre was carried on later in the U.K. in relation to many of the Normandy casualties.

In general, he felt that the chief lesson of his war experiences, as applied to civilian life, was the urgent and imperative need for creating filtration and rehabilitation centres in this country. In the sphere of treatment, narcosis and abreaction techniques have established themselves securely, but he felt that the latter would require patient evaluation in expert hands, otherwise it would fall into disrepute. The value of mechanized set-ups was not to be di regarded, and had their value in safeguarding the individual psychiatrist from fatigue. In particular he considered an insulin unit should always be available when handling psychotics, and he felt that the failure of many civilian authorities to provide such facilities was deplorable.

He suggested that the psychiatric problem would in all circumstances be found to be capable of analysis into six separate processes: Collection; filtration; treatment; rehabilitation; reallocation; disposal; and he pointed out the dangers of assuming that all psychiatrists were equally equipped by experience or temperament to perform all these tasks with success.

Major C. Kenton, R.A.M.C.: Forward psychiatry in the Army includes in its scope the consideration of, and the methods of dealing with, the problems affecting the mental health and morale of troops that are exposed, by reason of geographical propinquity, to actual, or closely threatened, enemy action. This view brings into focus the prophylactic as well as the therapeutic aspects of the subject while, at the same time, it limits consideration to the problems of soldiers fighting in an ill-defined and fluctuating, but nevertheless recognizable, area of military operations. Rarely elsewhere in the Army have group loyalties and group sanctions operated so intensely, or so profoundly, affected the military psychiatric outlook.

The prophylactic aspect of forward psychiatry may be briefly reviewed. Much can be done in this sphere by measures taken long before the entry of troops into the fighting area. I refer to adequate selection and screening, sound and intelligent training, promotion of good war purposiveness, good leadership, and the maintenance of efficient welfare for the troops. In the forward area these measures need to be continued, the Corps psychiatrist keeping himself informed of the changing problems, and advising on the steps to be taken to promote good morale and mental health, and the development of that degree of mental toughness essential in fighting troops. In addition he disseminates knowledge to regimental medical officers (and combatant officers) as to the causes and methods of psychiatric breakdown, how to check the incidence of such casualties, and how best to manage them when they do occur. The R.M.O. in helping to achieve these ends, acts as an integral part of the unit, and the close co-operation of the C.O. and company commanders is essential in the exercise of this good influence.

Notwithstanding the vigilance of those concerned with the prophylaxis against psychiatric breakdown, and how active and successful they are in the promotion of positive mental health and morale, it is still axiomatic that wherever fighting is in progress casualties of a psychiatric nature will occur, and that when the fighting is severe, the number of these casualties becomes such as to constitute a military problem. 10% to 15% of all living battle casualties are estimated to be psychiatric, and this figure is probably an understatement of the true position.

The military problem arising from this type of battle casualty resolves itself into: (a) preventing psychiatric casualties from impeding (i) actual fighting operations, (ii) the evacuation and treatment of the wounded; (b) selection and treatment of that proportion of men from the stream of psychiatric casualties who will be capable of early return to further effective fighting; (c) the prevention of deterioration in those unable to return early, or at all, to further fighting duty; (d) the factor of long-term conservation of man-power.

The therapeutic aim of forward psychiatry is to handle this military problem effectively in its early phase, and the methods adopted may now be discussed. The R.M.O., who first sees the psychiatric casualties, may, in very mild cases, send them back to their Company, after exhibiting a judicious mixture of firmness, sympathy, and friendly encouragement adapted to the individual case, and determined by his previous knowledge of the temperament and background of the individual soldiers under his medical charge. The decision to evacuate a case or to return him to duty is made by the R.M.O. acting as an integral part of his unit, and he is therefore guided by other factors in addition to the type and degree of psychiatric disturbance present. Some of these factors are: The military needs of the Unit at the moment; whether the soldier is still of some immediate use; the length of time the battle has been on; the state of morale in the Unit at the time; and the interests of the individual soldier.

If the decision to evacuate is taken, the diagnosis made is the purely "administrative" one of "exhaustion", and some notes from the platoon or company commander as to the circumstances of the breakdown are included, under sealed cover, with the field medical card. To all who are tremulous, apprehensive or agitated, a sedative such as Tab. Phenobarb. grain one or two is given. The sedation is continued at either the A.D.S. or M.D.S. in which the patient is staged *en route* for the Corps Exhaustion Centre. Phenobarb. grain one, three times daily is usually sufficient to keep the patient fairly quiet, relieve some of his distress, diminish the chance of his panicking, and prevent fixation of symptoms and further deterioration.

All those evacuated from the line with the diagnosis of "exhaustion" are speedily directed to a Corps exhaustion centre, which is usually a section of a specially selected field ambulance or C.C.S., and has a fluctuating number of beds. In this collecting centre major triage (or filtration) of the cases is undertaken, immediately after the essential needs of the soldier—a hot meal, a clean up of his usually dirty state, and attention to his bowels—have been fulfilled. This triage is based on a psychiatric interview in which a largely intuitive appraisal is made as to whether the soldier will soon be able to fight again or not. No definite criteria which help the psychiatrist in arriving at this judgment can be formulated easily, but the multitude of small component impressions obtained during the interview by an experienced Corps psychiatrist arouses the intuitive feeling of conviction that a soldier will or will not shortly be able to function effectively under conditions productive of great fear. In all those cases in which it is considered there is no reasonable probability of return to fighting duty within about five days, further sedative is administered, and they are evacuated to the advanced psychiatric centre. The diagnosis of "exhaustion" is abandoned and one which fits as nearly as possible into the nomenclature of diseases is made for each case. This is no easy matter

at times, particularly when otherwise normal soldiers of low "anxiety threshold" or low "anxiety tolerance" which renders them ineffective as combatants, need to be labelled with a psychiatric disorder to ensure their evacuation from the forward zone and their subsequent, more adequate, placement.

All those cases in which a reasonable probability of early return to fighting duty exists are retained for treatment at the Corps exhaustion centre. The principles underlying this treatment consist of: (a) continuation of, or increase in, sedation where indicated; (b) maintenance of military, rather than hospital patient, type of discipline; (c) continued contact with fellow-soldiers of the same or neighbouring fighting units; (d) some bolstering up of ego and morale; (e) maintenance of a curative atmosphere, so that early return to duty is expected by each soldier under treatment. Not all the cases retained at the centre prove fit to return to duty in the prescribed period, and these require to be evacuated to the advanced psychiatric centre. Figures of the proportion of cases admitted to the Corps exhaustion centre that can be returned to early fighting duty vary from Corps to Corps in the same and different theatres of war, and in the same Corps in varying conditions of warfare. The average proportion is rather less than 30%, the remaining 70% being evacuated to the advanced psychiatric centre. One of the major difficulties in this triage and treatment at the Corps exhaustion centre is that at the time of great operational activity, cases arrive at such a rate at the centre that the staff are rushed unduly and the optimum level of time for treatment often cannot be made available. This results in evacuation of some cases that would otherwise be unnecessary and unwise. In my opinion the Corps exhaustion centre is not the place for abreactive therapy, however tempting it may be in some cases. Such cases usually require much further psychotherapy and are best evacuated immediately to the advanced psychiatric centre without initiating any of the treatment other than continuation of sedation.

In the advanced psychiatric centre, therapy is less standardized and more definitely individual, although the patient is not regarded as completely detached from the group to which he has his loyalties and which imposes its sanctions upon him. A fairly high proportion of the cases are already improving and presenting a diminishing degree of psychiatric disability on admission to the centre. Treatment of these cases consists in appropriate instances, of rest, mild sedation with paraldehyde or barbiturates, alone or in combination, and one or two psychiatric interviews which have both a therapeutic and appraising function. Some cases are given insulin and glucose and extra diet to make up the loss of weight where this has occurred. A few cases, where the evidence of exhaustion is still apparent, are subjected to continuous narcosis of variable duration—sommifaine with paraldehyde supplement or the paraldehyde-phenobarbitone combination being the drugs we commonly used. A carefully worked out programme of occupational and diversional therapy, physical training, group activities of the leaderless type, and entertainment is made available for the patients, and they respond so well, even eagerly, to such a regime, that compulsion is almost never necessary. Within a period of ten to fourteen days this group of cases are discharged from the Centre, their destination depending on the appraisal by the psychiatrist as to (a) their probable effectiveness as fighting troops in the immediate future or (b) failing this, whether they need temporary or more permanent jobs not involving actual combat activities. Approximately 10% of the admissions to the centre come into the first category, and these cases are sent to the Army rehabilitation centre—which is not a medical unit—for a short period of military training and toughening prior to return to fighting duty. Those in the second category are despatched to a reallocation centre where they are interviewed and tested by personnel selection staff to determine their aptitudes and abilities with a view to satisfactory placement within the theatre. The majority of these cases in the second category are usually medically regraded, as a necessary precaution to prevent their too precipitate use as fighting troops.

The more severe cases require a therapeutic programme of greater complexity for their treatment and rehabilitation. Fortunately they form a minority of the case-load in the advanced psychiatric centre. Severe anxiety states, particularly when associated with mutism, stupor and other regressive manifestations, and amnesic states are treated by abreactive methods in the first place. I consider sodium pentothal as the most valuable agent for this purpose. The shorter induction period and less prolonged duration of effect of this drug are advantages as compared with sodium amytal. The technique, apart from slow intravenous injection ceasing just before actual sleep is produced, is varied in each individual case, the aim being the release of the emotions connected with the traumatic experiences. Whether these experiences are re-enacted or merely recalled, or whether they are not entirely factual but have an admixture of phantasy, is not very material, as long as suitable, repressed emotion related to these experiences is released, and the more or less overwhelmed ego can resume its functions. I prefer to release this emotion in one sitting, but my American colleagues favoured such release in controlled quantities. The response to abreactive therapy in severe battle-precipitated neuroses is usually dramatic and spectacular; but, in effect, ego control is still weak, although beginning to function. Strengthening of this control is aided by a direct, necessarily brief, psychotherapy, utilizing transference and explanatory techniques. Occasionally convulsive shock therapy succeeds where psychotherapy fails. Concurrently with this psychotherapy, the ancillary methods of occupational therapy, physical rehabilitation, and group activities are all used. A fair proportion of the severe cases are rendered fit enough by these methods to be sent to the reallocation centre for placement in non-combatant jobs. Those that are not considered fit enough, together with psychotics

The prophylactic aspect of forward psychiatry may be briefly reviewed. Much can be done in this sphere by measures taken long before the entry of troops into the fighting area. I refer to adequate selection and screening, sound and intelligent training, promotion of good war purposiveness, good leadership, and the maintenance of efficient welfare for the troops. In the forward area these measures need to be continued, the Corps psychiatrist keeping himself informed of the changing problems, and advising on the steps to be taken to promote good morale and mental health, and the development of that degree of mental toughness essential in fighting troops. In addition he disseminates knowledge to regimental medical officers (and combatant officers) as to the causes and methods of psychiatric breakdown, how to check the incidence of such casualties, and how best to manage them when they do occur. The R.M.O. in helping to achieve these ends, acts as an integral part of the unit, and the close co-operation of the C.O. and company commanders is essential in the exercise of this good influence.

Notwithstanding the vigilance of those concerned with the prophylaxis against psychiatric breakdown, and how active and successful they are in the promotion of positive mental health and morale, it is still axiomatic that wherever fighting is in progress casualties of a psychiatric nature will occur, and that when the fighting is severe, the number of these casualties becomes such as to constitute a military problem. 10% to 15% of all living battle casualties are estimated to be psychiatric, and this figure is probably an understatement of the true position.

The military problem arising from this type of battle casualty resolves itself into: (a) preventing psychiatric casualties from impeding (i) actual fighting operations, (ii) the evacuation and treatment of the wounded; (b) selection and treatment of that proportion of men from the stream of psychiatric casualties who will be capable of early return to further effective fighting; (c) the prevention of deterioration in those unable to return early, or at all, to further fighting duty; (d) the factor of long-term conservation of man-power.

The therapeutic aim of forward psychiatry is to handle this military problem effectively in its early phase, and the methods adopted may now be discussed. The R.M.O., who first sees the psychiatric casualties, may, in very mild cases, send them back to their Company, after exhibiting a judicious mixture of firmness, sympathy, and friendly encouragement adapted to the individual case, and determined by his previous knowledge of the temperament and background of the individual soldiers under his medical charge. The decision to evacuate a case or to return him to duty is made by the R.M.O. acting as an integral part of his unit, and he is therefore guided by other factors in addition to the type and degree of psychiatric disturbance present. Some of these factors are: The military needs of the Unit at the moment; whether the soldier is still of some immediate use; the length of time the battle has been on; the state of morale in the Unit at the time; and the interests of the individual soldier.

If the decision to evacuate is taken, the diagnosis made is the purely "administrative" one of "exhaustion", and some notes from the platoon or company commander as to the circumstances of the breakdown are included, under sealed cover, with the field medical card. To all who are tremulous, apprehensive or agitated, a sedative such as Tab. Phenobarb. grain one or two is given. The sedation is continued at either the A.D.S. or M.D.S. in which the patient is staged *en route* for the Corps Exhaustion Centre. Phenobarb. grain one, three times daily is usually sufficient to keep the patient fairly quiet, relieve some of his distress, diminish the chance of his panicking, and prevent fixation of symptoms and further deterioration.

All those evacuated from the line with the diagnosis of "exhaustion" are speedily directed to a Corps exhaustion centre, which is usually a section of a specially selected field ambulance or C.C.S., and has a fluctuating number of beds. In this collecting centre major triage (or filtration) of the cases is undertaken, immediately after the essential needs of the soldier—a hot meal, a clean up of his usually dirty state, and attention to his bowels—have been fulfilled. This triage is based on a psychiatric interview in which a largely intuitive appraisal is made as to whether the soldier will soon be able to fight again or not. No definite criteria which help the psychiatrist in arriving at this judgment can be formulated easily, but the multitude of small component impressions obtained during the interview by an experienced Corps psychiatrist arouses the intuitive feeling of conviction that a soldier will or will not shortly be able to function effectively under conditions productive of great fear. In all those cases in which it is considered there is no reasonable probability of return to fighting duty within about five days, further sedative is administered, and they are evacuated to the advanced psychiatric centre. The diagnosis of "exhaustion" is abandoned and one which fits as nearly as possible into the nomenclature of diseases is made for each case. This is no easy matter

at times, particularly when otherwise normal soldiers of low "anxiety threshold" or low "anxiety tolerance" which renders them ineffective as combatants, need to be labelled with a psychiatric disorder to ensure their evacuation from the forward zone and their subsequent, more adequate, placement.

All those cases in which a reasonable probability of early return to fighting duty exists are retained for treatment at the Corps exhaustion centre. The principles underlying this treatment consist of: (a) continuation of, or increase in, sedation where indicated; (b) maintenance of military, rather than hospital patient, type of discipline; (c) continued contact with fellow-soldiers of the same or neighbouring fighting units; (d) some bolstering up of ego and morale; (e) maintenance of a curative atmosphere, so that early return to duty is expected by each soldier under treatment. Not all the cases retained at the centre prove fit to return to duty in the prescribed period, and these require to be evacuated to the advanced psychiatric centre. Figures of the proportion of cases admitted to the Corps exhaustion centre that can be returned to early fighting duty vary from Corps to Corps in the same and different theatres of war, and in the same Corps in varying conditions of warfare. The average proportion is rather less than 30%, the remaining 70% being evacuated to the advanced psychiatric centre. One of the major difficulties in this triage and treatment at the Corps exhaustion centre is that at the time of great operational activity, cases arrive at such a rate at the centre that the staff are rushed unduly and the optimum level of time for treatment often cannot be made available. This results in evacuation of some cases that would otherwise be unnecessary and unwise. In my opinion the Corps exhaustion centre is not the place for abreactive therapy, however tempting it may be in some cases. Such cases usually require much further psychotherapy and are best evacuated immediately to the advanced psychiatric centre without initiating any of the treatment other than continuation of sedation.

In the advanced psychiatric centre, therapy is less standardized and more definitely individual, although the patient is not regarded as completely detached from the group to which he has his loyalties and which imposes its sanctions upon him. A fairly high proportion of the cases are already improving and presenting a diminishing degree of psychiatric disability on admission to the centre. Treatment of these cases consists in appropriate instances, of rest, mild sedation with paraldehyde or barbiturates, alone or in combination, and one or two psychiatric interviews which have both a therapeutic and appraising function. Some cases are given insulin and glucose and extra diet to make up the loss of weight where this has occurred. A few cases, where the evidence of exhaustion is still apparent, are subjected to continuous narcosis of variable duration—somniafine with paraldehyde supplement or the paraldehyde-phenobarbitone combination being the drugs we commonly used. A carefully worked out programme of occupational and diversional therapy, physical training, group activities of the leaderless type, and entertainment is made available for the patients, and they respond so well, even eagerly, to such a regime, that compulsion is almost never necessary. Within a period of ten to fourteen days this group of cases are discharged from the Centre, their destination depending on the appraisal by the psychiatrist as to (a) their probable effectiveness as fighting troops in the immediate future or (b) failing this, whether they need temporary or more permanent jobs not involving actual combat activities. Approximately 10% of the admissions to the centre come into the first category, and these cases are sent to the Army rehabilitation centre—which is not a medical unit—for a short period of military training and toughening prior to return to fighting duty. Those in the second category are despatched to a reallocation centre where they are interviewed and tested by personnel selection staff to determine their aptitudes and abilities with a view to satisfactory placement within the theatre. The majority of these cases in the second category are usually medically regraded, as a necessary precaution to prevent their too precipitate use as fighting troops.

The more severe cases require a therapeutic programme of greater complexity for their treatment and rehabilitation. Fortunately they form a minority of the case-load in the advanced psychiatric centre. Severe anxiety states, particularly when associated with mutism, stupor and other regressive manifestations, and amnesic states are treated by abreactive methods in the first place. I consider sodium pentothal as the most valuable agent for this purpose. The shorter induction period and less prolonged duration of effect of this drug are advantages as compared with sodium amytal. The technique, apart from slow intravenous injection ceasing just before actual sleep is produced, is varied in each individual case, the aim being the release of the emotions connected with the traumatic experiences. Whether these experiences are re-enacted or merely recalled, or whether they are not entirely factual but have an admixture of phantasy, is not very material, as long as suitable, repressed emotion related to these experiences is released, and the more or less overwhelmed ego can resume its functions. I prefer to release this emotion in one sitting, but my American colleagues favoured such release in controlled quantities. The response to abreactive therapy in severe battle-precipitated neuroses is usually dramatic and spectacular; but, in effect, ego control is still weak, although beginning to function. Strengthening of this control is aided by a direct, necessarily brief, psychotherapy, utilizing transference and explanatory techniques. Occasionally convulsive shock therapy succeeds where psychotherapy fails. Concurrently with this psychotherapy, the ancillary methods of occupational therapy, physical rehabilitation, and group activities are all used. A fair proportion of the severe cases are rendered fit enough by these methods to be sent to the reallocation centre for placement in non-combatant jobs. Those that are not considered fit enough, together with psychotics

and gross psychopaths, are evacuated to a rear (or base) psychiatric centre for long-term treatment or invaliding to the U.K. This group forms approximately 10% to 12% of the admissions to the advanced psychiatric centre, and their handling at the rear centre is outside the scope of the present subject.

From what I have said, it can be seen that at the separate organization levels, limited therapeutic goals are aimed at, varying with the different levels. Despite this stratification, I hope I have indicated the dynamic approach to the problem which is manifested by the psychiatrists in the field and their attempts to deal with the realities of the situation confronting them.

A brief reference may be made as to the results obtained by the methods of handling and treatment I have described. The figures for the N. African and Italian campaigns up to September 1944 for all cases where the disposal has been recorded, and including cases seen at all levels, show that of 22,454 patients 18,777 (83.6%) were retained for duty in the theatre of war and 3,677 (16.4%) were invalided home. Of those retained for duty in the theatre, no exact figure can be given for soldiers that were re-employed in active fighting duties, but it is in the region of 30% to 35%.

Lieut.-Colonel H. B. Craigie, R.A.M.C.: In view of the remarkable advances made in instruments of mutilation and destruction during the recent war, and of the extremes of mental and physical stress to which so many men were exposed, the percentage incidence of psychiatric breakdown was less than might have been expected. The numerical incidence, however, was sufficiently high to present a considerable problem; and much of it was avoidable, highly wasteful in its immediate effects, and potentially mischievous in its end-results.

In psychiatry as elsewhere, prevention is better than cure; and prevention, to be effective, depends upon an adequate understanding of the causes of psychiatric breakdown. In practice, there was rarely any single cause for breakdown in forward areas: the causative factors varied according to the individual himself, the group in which he functioned, and the environment by which he was surrounded.

A faulty personal history, a constitutional predisposition to neurosis, was the most important single factor in the causation of breakdown: if associated with a broken home life, or a faulty family history, the prognosis was so much the worse. "The qualities of a man that make him the best citizen", said Marshal Foch, "are those that make him the best soldier"; and this underlies the principles of personnel and officer selection employed in the Army since 1941. Men must be selected for service positively, not just because they have proved useless for anything else.

The individual's ultimate success or failure depended largely upon the group of which he became a member. High group morale depended upon proper training, upon knowledge of and devotion to the cause, upon adequate equipment, and upon inspired leadership. Good leadership, high morale, and a low psychiatric casualty rate were synonymous.

The environment provided the final test; and it was found that battle stress alone was neither the most common nor the most important cause of breakdown in forward areas; there was, in fact no fundamental difference between the causes of breakdown in forward and in base areas. Brigadier James said very aptly—"men break down for fear of life, not of death": and indirect mental or physical stresses were often much more significant in their effect upon the soldier than combat itself. Loss of sleep and physical exhaustion, persistent and overwhelming noise, thirst, hunger and dirt, physical ill-health, the inability to retaliate at the enemy, were associated factors of great importance. The factor of greatest and most universal application was the so-called "separation anxiety". Domestic separation was of the greatest importance to the average soldier; the longer in time, the further in space, the separation, the greater the anxiety.

Mental hygiene, the care of the mental health of the Army, proved during the war in many respects more important than physical hygiene; and its importance is at least equal in application to the community at peace. It is reasonable to assume that psychiatrists, in the light of the experience gained in these matters during war, may be able to make contributions of value to the solution of the very similar problems confronting us in the post-war years.

Lieut.-Colonel T. F. Main, R.A.M.C.: In the forward psychiatric centre, therapeutic practice should, one supposes, remain objective, illumined only by psychiatric knowledge. It would be nice to report that in the forward areas psychiatry is cool and accurate and unimpassioned. But if we take thought for an instant we can see that this can never be so. Psychiatric disease and normality are only relative matters affected by current social standards and culture patterns. An emotional state which might at home be

described legitimately as severe anxiety, might on the field be called bravery or cowardice depending on whether the psychiatrist himself is frightened or not.

A forceful moral diagnosis is therefore sometimes made by the psychiatrist before he applies the new nomenclature of the Royal College of Physicians, and treatment is sometimes affected by the psychiatrist's needs as well as by the patient's.

Other influences also affect objectivity. There is an understandable general desire during a war to feel important and useful. The inevitable hardships and sacrifices of war affect everyone to some extent, and lead to various emotional by-products of bitterness and impotence, anger, and—if one's own job is not heroic or important enough—to defensive swashbuckling or a guilt-driven compassion for the others who have to undertake risks of death in battle. Sentimentality and anger about neurotic soldiers, therefore, commonly influence clinical judgment in prognosis and disposal.

Now if the judgment of psychiatrists is liable to lack objectivity in the face of great world events, it must not surprise us if excessive emotions also arise in others. Violent attitudes in medical colleagues and superior officers are part of the total social setting within which the psychiatrist works and influence for better or worse his daily judgment and his over-all policy.

The mental health of a fighting force is not the same thing as the mental health of a nation at war. With the differing functions, different standards are needed. If a sergeant can recover his poise for one month, it can be regarded as a satisfactory therapeutic result in an Army fighting for its very life, though such a result would not be worth having in civilian life. Then the stresses which such a man must be capable of withstanding are very different from those which would operate upon him in civilian life—and they must be fully understood by the psychiatrist. Lastly, the positive factors which will support the mental health of such a man are different in the forward area from those in the rear areas. The job of the psychiatrist, in fact, demands a grasp of the social as well as the medical variants which influence treatment and disposal.

One campaign does not seem to train a psychiatrist automatically for another. In the Middle East the great separation from home, the flat barren wilderness in which the men lived, the poor food and water supply, the rarity of action, the occasional big battles dominated by the spandau, the 88 mm. and the mortar, lasting only a few days, contrast with the battles of the Normandy Bridgehead which went on without remission for over two months in familiar green fields and copses, with scarcity of sleep, the multi-barrelled mortar, and the continued carnage as the great stresses. In Burma, I am told, it was not the noise of explosions nor the power of enemy weapons that were the stresses, but silence in jungle patrols, the fear of being seen without seeing, the difficulty of sleeping with a calm mind, and the long separation from home.

Yet these stresses can be classified. The sense of separation from home, from its security and its comforting permanence and its familiar reassurance of one's personal status is a permanent stress. A camaraderie is the only human recompense for a threatening sense of impotence in the face of death and the waywardness of elemental forces and the decisions of the mighty who use soldiers like pawns.

The lonely homesick man, overwhelmed by insecurity, showing anxiety and hysterical illness, is met sometimes before he has even been in battle, together with the men who have carried out their social obligations in the face of fantastic dangers until their sense of security too has gone. There are others who have contained their anxiety, supported by comradeship and affection until the death of their friends has left them bereaved, to face further dangers alone. The man who has killed too much, the officer who has lost his men through an error of judgment, the tank commander who escaped alone from a burning tank—present pictures of guilt and depression that may be psychotic in depth. Fleeting schizophrenic screens may be drawn for a few days over anguish too gross to be borne.

These acute clinical pictures arise very often in conjunction with loss of sleep. While this can be a symptom it is often a necessary condition of some battles, and gross fatigue alone leads some men to the psychiatrist.

Acute cases repay the simple forward treatment of rest and sedation and justify the existence of forward psychiatric centres. The bonds which tie men to their fellows have not yet been broken, and some 30% to 60% can be returned fit to carry on. The numbers correlate indirectly with the surgical casualties—following about 3 days behind the curve of daily incidence. But it is not a parallel curve; as the surgical casualties rise, the psychiatric casualties rise out of all proportion. Depending on the type of battle, 2% to 30% of all casualties may be psychiatric.

When the numbers are high during a big battle, you may imagine the alarm in high places, the increase in diagnosis of "cowardice" by administrative staffs, and the reluctance to recognize the problem as a psychiatric one. At these times all the slack in senior super-egos is taken in, and some of the wrath falls of course on the patients and occasionally even on their therapist. That is in the day's work. One popular view at such times—popular in rear areas at least—is that access to the psychiatrist will discourage the fighting men who are sticking it out. This may be so, but I have yet to meet a regimental medical officer who knows of a single instance of a good man being discouraged by the knowledge that if he became a casualty of any sort he would get looked after.

The "chronic" cases seen in quiet periods are a mixed bag. Some of them are chronic neurotics, but many are men with persistent symptoms from earlier battles, particularly of guilt and depression about comrade-loss or with anxiety which has not resolved spontaneously after rest. The home worries, too, mount as a campaign goes on and become increasingly a source of military inefficiency. The prognosis with the cases that appear during quiet periods is not as good as with the acute cases, and hospital treatment and re-allocation are needed.

The forward psychiatrist has made himself a familiar figure in the war, and has proved his value in every theatre since 1940. He cannot work miracles, but by persistently plying his craft, keeping his head amid the shifting moral attitudes towards his patients, and remaining, in so far as his own situation allows, objective and unsentimental, honest about his failures and modest about his successes, he can serve the men of his formation in a way granted to few medical men. Such a result, however, is achieved not by heroics, but by good psychiatry.

[December 11, 1945]

DISCUSSION ON THE IMPORTANCE OF DIET IN MENTAL ILLNESS

Dr. W. Rees Thomas: For many years pellagra has occurred in this country, arising as occasional cases in the community and among patients in mental hospitals. In the early days, before the cause of pellagra was known, we described a dermatitis of the hands and face resulting from the administration of drugs such as sulphonamide and trional. We know now that this was pellagra and it arose not only from a deficient intake of vitamins of the B group, but also from a failure of the body mechanism to absorb it or, if absorbed, to use it for its proper purposes. To-day we know of occasional cases of pellagra arising in mental hospitals, though most of the cases reported were admitted suffering from the disease. I am not proposing, however, to deal with specific diseases arising from food deficiencies but with the more general relationship between health and food, and in particular its effect on patients undergoing treatment for mental illness. How far this may have an influence on accelerating or retarding recovery in mental illness is a matter which we could discuss without forming a definite conclusion. It can, however, be said that subnormal food must lead to subnormal health. The outstanding example is the effect of vitamin C on the healing of wounds, and I feel sure there would be general agreement that in the treatment of any form of mental illness a factor of importance is the quantity and relative sufficiency of the food; the caloric value is important for patients who are not confined to bed or who exhibit considerable physical activity as part of the illness.

Shortly after the outbreak of war in 1939 most of us discovered that we were losing weight. A similar phenomenon occurred in mental hospitals. The change was so obvious that in 1941 an investigation was made to determine whether gains and losses of weight differed from changes occurring in the same patients during the two years before the outbreak.

In seventeen hospitals the weight records between September 1937 and September 1941 were examined. The figures indicated that the loss of weight in the period 1939-41 had been very considerable and affected quite three-quarters of the patients who had been in the hospital during the whole period. This is not quite so bad as it sounds; the peacetime figures show that normally 45 to 50% of the patients tend to lose weight over a period of two years. This is a selected group consisting entirely of those whose illness is prolonged.

The hospitals were divided into two groups, depending on whether or not they were overcrowded. Comparison of the records of loss of weight showed that the degree of

overcrowding existing at the time made no difference to the proportion of patients who lost weight.

At a later date a further investigation was carried out by Dr. Nicole at the Winwick Mental Hospital. The results indicated that from 1942 onwards the position gave no cause for anxiety. The proportion losing weight had greatly diminished and did not differ widely from the figures for the period 1937-39. It is difficult to say just why this change took place but in 1942 we became more food conscious and everybody did a good deal to improve the variety, the quantity, and the balance of the diets, and hospitals were now able, without much trouble to themselves, to have the diets analysed and the quantity of vitamins and minerals estimated as a daily average over a period of one month.

I will now refer to the general food situation during the war up to 1943 as related in "Food Consumption Levels (1944)". The daily caloric value of the food supplied to the people of this country before the war was about 3,000. In 1939-41 there was a sharp fall in the meat, visible fats, sugar and fruit which greatly reduced the palatability, as well as the nutritional, value of food. At the period of greatest shortage in the first half of 1941 calories fell to 2,680 and it appears that there were indications that the diet was inadequate. In 1942 the figures showed an improvement and from then onwards have remained almost constant at a caloric value of about 2,800, though fats and animal proteins remain considerably below pre-war level. The importance of this for my present purpose is to indicate that in 1941 the food was not sufficient and in 1942 and onwards it can therefore have only been slightly above the level of sufficiency. These figures do not represent the actual intake of food but of food issued for consumption.

A comparison of these two events, that is the loss of weight and the standard of food issues, suggests that the reduction of food supplies showed itself in a loss of weight amongst the hospital population—at least that part of it represented by patients undergoing prolonged treatment. The recovery from 1942 onwards is parallel to a better food situation and a time of greater attention to the minerals and vitamins as well as the caloric value of the foods supplied. There are, however, many other factors to be taken into account, though none of them can easily account for the initial loss of weight to the end of 1941 and the subsequent recovery.

I go on now to consider the effect food may have on the death-rate in hospitals. We have lived through two great wars and an examination of the death-rates in hospitals during these periods may show that diet in one war affected the death-rate. The mean death-rate in mental hospitals for the five-year period 1910-14 was 96 per thousand, and the death-rate during the years 1915-21 given in the table below might be compared with this pre-war figure. The table also indicates similar data for the years around the war 1939-44.

TABLE I.—DEATHS PER THOUSAND.

	General population	Mental hospitals		General population	Mental hospitals
1910-14	13.8	96	1935-39	12.1	68.5
1915	15.7	121	1940	14.4	82.6
1916	14.3	126	1941	13.15	91.7
1917	14.2	176	1942	12.3	79.9
1918	17.3	203	1943	13.0	69.8
1919	14.0	129	1944	12.7	69.0
1920	12.4	87			
1921	12.1	84			

A comparison between the two sets of figures shows very marked differences. During the period 1915-18 there was a progressive rise in the mental hospital death-rate throughout.

The abrupt fall in the death-rate in 1919 and the further reduction in 1920 to a figure well below the 1910-14 rate shows that conditions improved rapidly after the war, and that within a year they were normal again.

During the recent war, the death-rate increased in 1941 to a rate which was 33% higher than the pre-war average, and thereafter slowly fell to a figure which in 1944 was only slightly above the rate for 1935-39, i.e. 69 compared with 68.5.

The figures for men and women are given separately in the second table; they show that for women the rate fell in 1943 to 64, which, excepting for the years 1930 (60.6) and 1938 (61.8), is the lowest ever recorded.

TABLE II.—PROPORTION PER CENT. OF DEATHS TO AVERAGE NUMBER RESIDENT.

	Male	Female	Total
1937	7.09	6.04	7.0
1938	6.82	6.18	6.47*
1939	7.05	6.86	7.21
1940	8.06	7.04	8.26
1941	10.46	8.21	9.17
1942	8.81	7.36	7.99
1943	7.74	6.40	6.98
1944	7.49	6.46	6.90

* Lowest ever recorded.

It is noteworthy that this occurred at a period when the shortage of female nurses was greater than at any time during the century.

If we consider for a moment the factors which might have affected the death-rates during these wars we find that during both periods there were certain common stresses and strains.

Overcrowding occurred in both periods in the early war years. In the first war, however, the death-rate was so high that overcrowding was much reduced in the later years. Black-out restrictions were much more severe in the recent war, resulting in a low standard of ventilation in dormitories and bedrooms.

Changes in the ages and types of patients admitted would be similar in both wars.

If shortage of staff had been an important factor in determining the death-rate it would have showed results on the women's side of our mental hospitals during the past three years. Though I am unable to quote exact figures for the period 1914-18 I am assured that at no time during the 1914-18 war was the staff shortage on the female side as acute as it has become during this period when so much woman-labour was diverted to factories producing munitions of war.

Enemy action and the disturbance to patients caused by "alerts" undoubtedly produced abnormal conditions, but we can agree that on the whole the stress during 1940-41, particularly in certain areas in the East and South, was greater than that caused by Zeppelin raids.

On the whole, then, it would seem that the stresses in the recent war were more severe, due to equal, if not greater, overcrowding, stricter black-out regulations, inferior ventilation at night, greater shortage of both male and female staff, and much mental and physical strain arising from enemy air action by night. The causes of the high death-rate in the 1914-18 period were the subject of an investigation by the Board of Control. They concluded that the unavoidable reduction in quantity and deterioration in quality of the food supplied to patients (especially in regard to flour) were the main factors in determining the increase in sickness and corresponding increase in death-rates among patients in institutions for the insane and defective; but that, had the diet been normal, there would still have been a considerable rise over pre-war rates due to other war conditions. The conditions referred to were the lower physical condition and greater age of patients admitted, the impairment of staff efficiency, transfer of patients from one mental hospital to another, and overcrowding combined with bad ventilation. I think it is reasonable to assume that the difference between the records in the two wars shows something of the advance in knowledge of food and feeding.

An analysis of the dietaries of some two-thirds of the hundred or so mental hospitals in this country was carried out during the recent war. Each hospital publishes an official dietary with menus running a three or four weeks' rota. We found that these dietaries gave an incorrect and exceptionally rosy picture of the situation; consequently the analysis was made on the basis of the actual issues of food to the kitchen, taken from the records in the weekly issue books in the stores department. There were certain difficulties in carrying out the analysis because the extra food given to certain patients known as "workers" had to be excluded from the general issue and naturally diet given to sick patients had to be left out of account. The number of working patients given extra food varied within wide limits; of the 83,000 patients concerned some 27% of them received an average caloric value of 290 per day as an extra. An additional 10% of the patients were in receipt either of sick diet or of some extra to ordinary diet. The remaining 63% received the ordinary diet with nothing extra: the mean caloric value of the ordinary diet was 2,360, ranging from 1,956 to 2,731 calories a day. Vitamin A was 2,110 international units, and vitamin C 85 mg. per person each day.

It is not easy to say what should be the caloric value of a diet issued to a group of adult patients many of whom are quite old and many physically as well as mentally ill.

The average figure of 2,360 indicates that the patients of about half the hospitals receive less than this amount. The present evidence indicates that the food is sufficient providing that the distribution between wards takes account of the type and activity of the patients in their classified groups.

In considering whether a diet is adequate we base our views on the relation of the quantities to standards which have been set up by the National Research Council of the U.S.A., which has approved a minimum standard applicable only to short term periods but which provides mineral and vitamin allowances approximately 70% of the ordinary standard. In 1943 a special committee of the Joint Food Board, as quoted in "Food Consumption Levels, 1944", thought that the diet in this country, with the exception perhaps of vitamin A and ascorbic acid, and possibly also of riboflavin and thiamin, was adequate to meet the intake requirements based on the full National Research Council standards. Diets in mental hospitals provide a sufficiency of calcium, iron and vitamins of the B group.

There is an important difference between the food issued to the general population and that supplied in a mental hospital. The maintenance of a satisfactory level of calories and vitamins in the United Kingdom diets has involved a substantial increase in the use of cereals and potatoes. In 1943 this contributed 43% of the total caloric supply compared with 34% before the war. For the mental hospital, however, the present figure is between 50% and 60% and consequently the supply of potatoes ensures, at least in the summer time, an adequate ration of ascorbic acid. Even throughout the winter months the supply of vitamin C has exceeded 58 mg. per head per day, largely through the use of leafy, yellow and green vegetables. As the losses during cooking and preparation are considerable the intake in winter would not exceed an average of 30 mg. of ascorbic acid.

The supply of vitamin A is obtained largely from fats, milk, growing vegetables, eggs, and carrots. The ordinary diet in most mental hospitals provides about half the supply from carrots, the remainder coming from miscellaneous items of food. The mean figure of 2,110 I.U. per day showed that in most hospitals the supply of vitamin A was below the optimum level. The deficiency can be made good by the use of about half a pound of carrots per patient per week. Carrot is not available in every week of the year, but as vitamin A is stored for considerable periods in the liver, irregularity of supply is not a matter of vital importance.

The average mental hospital has one advantage over the many other hospitals. There are farms from which the supply of milk for patients comes daily to the hospital. The quantity available for the ordinary diet has usually been ample, and in this respect they have been more fortunate than the general population.

The suggestion that diet can be maintained at a satisfactory level without great difficulty does not affect the much more difficult question of cooking and presentation. The common complaint is lack of variety and though we, as members of the population, complain of the same thing we do not suffer in the same degree. Repetition in the presentation of the same items of food makes food unpalatable and the patients' inability to take an occasional meal outside the hospital tends to lower appetite. All this leads to waste and a lowering of the caloric value of the food intake. The patient suffering from mental illness is often too busy to bother about food or too depressed to want it. Thus with a supply of food that is adequate though little above the minimum it behoves us in every case of mental illness to pay the closest attention to the details of presentation and variety as well as to the quantity and content of the food taken. Our scientists teach us that even in a time of plenty a diet cannot be taken for granted even when the patient makes no complaint.

Dr. H. E. Magee: The Ministry of Food is advised regarding diet for invalids by the Special Diets Committee of the Medical Research Council on which the Ministry of Health is represented. This Committee gives medical advice as to whether patients suffering from any particular disease should have special allowances of rationed or other foods. The various allowances for different types of invalids are set out in the special leaflet, Med. 2, which has been sent to every medical practitioner. The Committee has not recommended any special priorities for mental patients as such. Mental patients, suffering from non-mental complaints such as diabetes or tuberculosis, are entitled to the prescribed allowances of rationed or other foods. Mental hospitals, like all others, can also obtain a priority allowance of 2 lb. fish weekly for every patient requiring a "light

diet". Apart from this allowance of fish mental hospitals are rationed like an ordinary institution for healthy people.

The requirements of the individual mental patient will vary with the amount of muscular exercise he performs. If he is doing farm work daily in the open air he would require a diet providing about 3,500 calories or more daily, but if he is quiet and confined indoors he might only require 2,400 calories or less. Other things being equal the needs of mental patients vary with their complaints. The melancholic or paranoic type might require only about 2,000 calories a day or less, whereas the excitable type with exaggerated reflexes, lack of co-ordination, continual unrest and insomnia might well require 4,000 calories a day. If the demands of such a person are not fully met it would seem from general principles that he would tend to become more rather than less excitable, at any rate for a time. The experiences of most people during air raids, particularly the V.I. bombardment, supports this deduction. The severe mental and physical strain with few interruptions, which most normal people experienced, were unquestionably reduced by taking small snacks in between the ordinary meals. It will be recalled that the Radio Doctor at this time advised people to eat often and to be sure to eat enough. I have no doubt that very many people derived much comfort from this advice.

Balancing up the needs of the various patients in a given mental hospital it is probable that the average gross requirement for the adult male is round about 3,000 calories per head daily and for women probably about 2,200. Within this average there will of course be wide fluctuations, but the allowances of food permitted and the mode of serving should be sufficiently elastic to permit of these needs being fully supplied. If the diet includes all the rations and points foods and if bread, potatoes, oatmeal and fresh vegetables are given to satisfaction, there need be no fear of any deficiency whether in regard to energy, proteins, minerals or vitamins. Table I shows how a 3,000 calorie diet could be constructed from the rationed and unrationed foods. Rationed foods, providing a sensible choice is made of the points, will supply about 1,040 calories and about 30 grammes protein most of which is of animal origin. The remaining 2,000 calories would have to be made up mainly from bread and flour which provide about 1,100 calories, or more than one-third of the total day's needs, and from potatoes and oatmeal, each of which provide about 220 calories or about one-thirteenth of the day's needs. The remaining calories would have to come from things like sausages, fish, and offal, when they can be obtained.

The unrationed foods provide about 72 grammes of protein, over twice that provided by the rationed foods. Bread and flour alone give as much as 41 grammes daily, whereas rationed meat only provides seven. It is true that animal protein is of higher biological value than any kind of vegetable protein, but vegetable proteins are also valuable. It is stated from time to time that the requirements of animal protein are so many grammes daily. There is no experimental evidence which enables us to place the requirements of animal protein at a given figure. Indeed we cannot say that the human body *requires* (in an indispensable sense) animal protein, at any rate after the stage of childhood has passed. In childhood there is, of course, a definite requirement, but for adults, all we can say is that it is very desirable that a proportion, which we cannot define, of the total protein should be of animal origin.

We often hear complaints that certain people, particularly hospital patients and staff, are not getting enough protein, that their diets are too starchy and therefore unsuitable. If you consider Table I you will find that this cannot happen, provided the people are getting all or the bulk of their rationed foods and provided the total diet gives them sufficient calories. To obtain a diet of sufficient calories which would be at the same time too low in protein, would not be easy; indeed with present rations it would be impossible. The calories would have to come from bacon, fats, sugar, jam and vegetables and fruit. The first four of these would provide only about 500 calories a day, and vegetables and fruit could certainly not provide the rest. It can be taken as a broad general rule that if a person of ordinary tastes consumes sufficient calories from the foods available he can scarcely avoid having enough protein, minerals and vitamins. In fact, the wartime food policy was so planned as to make this possible.

Table II shows the standard intakes of nutrients recommended by the Commission on Nutrition of the League of Nations as applied to the population of Great Britain. I have only given the figures for the adult man and woman because it is with these that we are mainly concerned. The calorie level for the average man is 3,000 and the protein 70 grammes a day. This is much lower than the 101 grammes which can be obtained from a 3,000 calorie diet under present rations. There is another scale of st

requirements in considerable vogue to-day, namely, that of the National Research Council of the U.S.A. It was drawn up in 1941 by the Americans but it has not received international approval. In regard to calories, proteins and minerals it is not substantially different from the scale of the League of Nations, but the scale for vitamins is far in excess of that of the League of Nations. Take vitamin C as an example. The N.R.C. recommends for children 5 to 14 years 50 to 75 mg. of vitamin C daily. Bransby and Wagner (*Brit. med. J.*, 1945 (ii), 682) found by dietary surveys that 426 school children in

	30	30	75	70

Stoke-on-Trent and Salford were consuming for most of the year an average of about 20 to 25 mg. of vitamin C daily. The school meals were analysed for vitamin C and they were found to contain only from 2 to 19 mg. per meal. The school meal for many children is the main, if not the only, source of vitamin C. These children were very carefully examined 3 or 4 times during the course of the year but no evidence of any sort was found suggestive of deficiency of vitamin C. There is other and more convincing evidence not yet published indicating that the recommended allowances of vitamins A and C of the N.R.C. are far too high, at any rate for the inhabitants of this island.

One of the most striking things that have come to light from liberated Europe is that frank deficiency disease, particularly vitamin deficiency, has been rarely observed whatever the degree or duration of the shortage of food. Nutritional œdema, loss of weight, diarrhoea and more rarely anæmia have been observed at various times and in various places, but very rarely pellagra, beri-beri, night blindness or other well-defined deficiency condition. What have always been observed however, whatever the degree or duration

of the starvation, were progressive asthenia, apathy, listlessness, lack of attention to personal hygiene, indifference to personal or communal welfare, until finally the sufferers became almost indifferent to their fate.

Without the will to live the treatment of a diseased person is a very up-hill and, may be, an impossible task. Insufficient food tends to blunt the desire to live. Adequate feeding tends to restore and to sharpen it. Good feeding besides building up the diseased body also enables the mind, which controls the body, to function properly.

In conclusion here are some observations made in 1942-43 in the (male) mental hospital of St. Anne in Paris by Randoin (*Bull. Acad. Méd.*, 1943, 127, 559). Before the war the average calorie intake was about 2,877 daily and the death-rate 10%; in 1941-42 the average calorie intake was about 1,750 and the death-rate 21%. On this level of diet the patients lost up to 5 kg. per head in six months, but when in 1943 the diet was increased all round by about 25% most of the losses in weight were restored in six months. This interesting paper has only recently come to my notice.

Dr. S. W. Hardwick said that he was not complacent about the question of diet and mental disorder. He believed that mental disorders associated with vitamin deficiencies were by no means uncommon. He had described in 1943 12 cases of pellagra complicating chronic mental disease and most of these were seen by Professor Sydenstricker during his visit to this country. Dr. Hardwick had encountered additional cases of pellagra in his mental hospital since then. He said that when Professor Sydenstricker with Dr. Rees Thomas had only seen one case of pellagra during their visit to a certain mental hospital—this did not necessarily mean that there was only one pellagrin in the population of that hospital at that time. There may have been cases showing no overt signs of pellagra at that time.

No mention had been made of acute vitamin deficiency. This was disappointing because it seemed that here was a field where the interests of the dietetic expert and the psychiatrist intersected. He referred for example to acute nicotinic acid (niacin) deficiency, a condition which had been described by Sydenstricker and Cleckley, and others. There was evidence, in Dr. Hardwick's opinion, that niacin deficiency, probably secondary to dietetic deficiency, was an important causative factor in some cases of mental illness.

In conclusion Dr. Hardwick mentioned that he had been associated with Professor Ellinger of the Lister Institute and Mr. R. Benesch in certain problems arising from vitamin deficiency. A nicotinamide saturation test had been devised, and this might lead the way to simpler and quicker methods of biochemical diagnosis.

Physical Medicine in the Army

Its Effect on Civil Practice. [Abstract]

PRESIDENT'S ADDRESS

By J. W. T. PATTERSON, M.D., F.R.C.P.Ed.

Late Lieut.-Colonel R.A.M.C., Late Assistant Director of Hygiene, War Office

THE post-war world, on whose threshold we stand to-day presents a very different picture from the one we knew before the war. New discoveries, new modes of thought and new social conditions challenge us on every side.

That challenge must be accepted and our first step is to take stock of where we stand. Only then may we determine what contribution Medicine, with its high traditions of service, can make in the changing world around us.

My contribution concerns itself with the development of Physical Medicine in the Army.

"Physical Medicine Specialists" in the Army started by advising on the individual rehabilitation of soldiers referred to military convalescent depots for retraining. Soon they were advising on "group" rehabilitation and then on the general progression of training within the depot.

Next came the study of rehabilitation methods *outside* the depot in order (a) to attempt to standardize the physical condition of men arriving at the depot from such variable sources as special chest hospitals, head injuries, general hospitals, orthopaedic hospitals and auxiliary hospitals; (b) to ensure that steady progression was maintained throughout from bedside, through initial convalescence, to convalescent depot and, at the other extreme, from convalescent depot to unit.

This latter necessitated a study of the relative demands made by varying employments in different units and a study of the training of the fit. This liaison with training authorities resulted in Physical Medicine giving advice on training and drawing up physical standards for the selection of special troops, e.g. parachutists, frogmen, &c.

Physical Medicine played an important part in the medical aspects of selection not only for the special troops but for the less fit personnel and was responsible for much of the spade work entailed in introducing the new system of Army Medical Classification which is to be a feature of the peacetime Army.

Physical Medicine, with the invaluable assistance of the Army Physical Training Corps, was responsible for the success of the physical development centres where thousands of recruits likely to break down under routine training were able to "make the grade" as A 1 personnel after special preliminary training.

Physical Medicine made considerable contributions to the large-scale investigation of various important problems relative to health and training and the study of the sub-standard recruit.

Such was the unfolding of the opportunities presented to Physical Medicine in the Army.

What may we say of the lessons we have learned from these experiences?

(1) That successful rehabilitation depends on a thorough co-ordination of all remedial measures from the bedside, through ambulatory convalescence, right up to final reinstatement.

(2) That reduction in the period of convalescence is just as important as the reduction in the duration of hospitalization. The latter has been brought home to the profession through the shortage of hospital accommodation. The former is equally important from the point of view of industry and from that of the patients' economic circumstances.

(3) That the medical profession must be prepared to study and disseminate knowledge in what are the most effective measures for rapid and complete restoration after disability and must be prepared to condemn all personal idiosyncrasies in regard to methods which are proved to be wasteful and less than fully effective.

(4) That successful rehabilitation demands a thorough knowledge of *all* the operations involved in the employment for which the individual is being prepared.

(5) That successful rehabilitation involves the rehabilitation of the *whole man*, psychological and social as well as physical.

(6) That the medical profession must be made to realize the importance of job analysis. It should busy itself with the investigation of job analysis from a medical point of view so that, among other considerations, its rehabilitation work shall be more purposeful and more scientific.

(7) That Medicine must be prepared to advise on the capacity in which a permanently disabled person may be most adequately and suitably employed.

(8) That Medicine must be brought to realize the importance of physical education and its interest and supervision enlisted in this highly effective factor in the maintenance and achievement of physical efficiency.

(9) That Medicine must be prepared to extend its preventive aspect more completely. It must investigate and adjudicate on all measures likely to improve and maintain health in addition to concentrating on established disease processes. Such a preventive outlook demands investigation of the so-called Normal, seeking to establish those ranges of normality, outside which preventive measures must be undertaken to avoid ultimate disability.

[Meeting held on March 14, 1945, at St. Thomas's Hospital, London. Continued from August issue of "Proceedings"]

The Use of X-rays in the Treatment of Indurations due to Scars and Chronic Inflammation

By R. D. S. RHYS-LEWIS, M.B., B.Chir., D.M.R.

A NUMBER of cases have been treated in this hospital with X-rays in conjunction with surgery and physical treatment. They showed persistent induration and scar formation following acute infections, and the object of treatment has been to hasten resolution of the induration and to restore the function of the affected part.

The ages of the patients treated ranged from 4 to 69 years, the majority being in the third and fourth decades. There was in all cases a history of an injury which had become septic, and in nearly all the injuries had occurred on the extremities. The tendon-sheaths had often been involved. Half the lesions were caused by penetrating wounds from enemy shells and bombs, the remainder occurred as a result of the hazards of industrial and everyday life.

The patients were referred for treatment from two to six months after the original injury, and had already been given surgical and physical treatment including the sulphonamides and penicillin. They fell into two main groups: (1) Chronic induration of the soft tissues following acute infection. (2) Thickened plaques of keloid scar-tissue often with deep attachment and limitation of movement.

The X-ray treatment of each type of case differs in many respects.

Treatment of Chronic Infections

When the acute stage of an infection of the soft tissues has settled down, there is often an indurated area where resolution is delayed. This can usually be successfully treated with X-rays where surgery, physical treatment and chemotherapy have failed, and the induration rapidly made to disappear.

Several theories have been put forward to explain the action of X-rays on inflammatory conditions.

It is probable that the effect of irradiation is not on the causative organism or agent, but on the morbid anatomical process produced in the tissues. Most authorities are agreed that the infiltrating leucocytes are very sensitive to X-rays and readily break down with the liberation of enzymes. In a focus of chronic inflammation the capillaries and tissue spaces are blocked by lymphocytes, which can be eliminated by a very small dose of X-rays and the blood supply correspondingly improved. The capillaries themselves dilate as a result of the direct action of the X-rays and a local passive hyperemia is thus produced.

There is a further view held by many authorities that non-specific antibodies are produced in the tissues which are subjected to irradiation.

The doses used are so small that the risk of damage to normal tissues is minimal.

Technique.—In the treatment of these cases, filtered X-rays of medium penetration generated at medium kilo-voltage are suitable. The field irradiated is sufficient, amply to cover the indurated area, and the dose given is small. We use here 50-100 r every four to five days. The number of treatments varies with the speed of resolution, but seldom are more than four or five treatments necessary.

There are no general constitutional effects on the patient and there should be no skin reaction. The induration usually resolves completely; the inconvenience is very slight as each attendance is only a matter of minutes.

The Treatment of Scars

These cases were mainly thickened scars following recent injuries or surgical intervention for complicated and infected wounds.

These scars showed keloid formation on the surface with firm induration deep to the scar composed of actively dividing cells and deep keloid formation.

The irradiation of such scars is followed after an interval of time by pallor and flattening of the surface keloid with softening of the underlying thickening and a resultant increase in mobility and restoration of the function of the affected part.

It might be mentioned that the irradiation of old contracted fibrous scars is not only useless, but unwise. They are very resistant to the action of X-rays, and high doses given in an attempt to influence them only result in an increase in fibrosis due to the action of the X-rays themselves or even in tissue damage and breakdown in the form of radionecrosis.

Technique.—The technique of irradiation of these scars has been evolved by many workers for both radium and X-rays, and with the advent of more satisfactory apparatus in recent years and careful physical calibration, it has been possible to work out an accurate form of treatment.

Between 1930 and 1942 much experimental and clinical work was done by Levitt and Gillies and the effects of increasing doses were studied. It was found that the best results were obtained by a very nice adjustment of the dosage, as evidenced by the biological effect of the production of a mild erythema of the scar. Such a reaction is necessary to produce the optimum result.

The field irradiated is confined to the scar, and, here, we have used filtered X-rays generated at potentials varying from 60 to 200 kV., according to the degree of penetration and quality of ray required. The usual kV. employed was 140, except where deep structures had to be avoided, when X-rays generated at a lower potential 60 kV. were preferred.

The dosage has been administered either as a single high dose to a small area or in fractionated doses if the area involved was large, or where it was desired to avoid constitutional effects on the patient, especially when high-voltage X-rays were employed.

A single dose of 500-800 r according to the site and size of field was given for all voltages, or 1,500-2,000 r in fractionated doses over periods varying from five to twenty-two days. No standardized "routine" treatment was thought advisable as the cases varied considerably in many respects and each was treated according to its merits.

In none of our cases has this treatment been repeated.

Contra-indications and Dangers of this Form of Therapy

In the treatment of indurations following infection, where small doses are used at intervals of several days, the risks attendant upon X-ray therapy are not very great. But in the treatment of thickened scars, where high dosage is used and medium and high-voltage X-rays often employed, there are many factors to be thought of.

The age and general condition of the patient must be taken into account. In the young, the injuries are often on the extremities and it must be remembered that the growing ends of bones underlying the scar area to be irradiated can be irreparably damaged by X-rays with resultant deformity such as brachydactyly. It is in such lesions that rays of low penetrating power are indicated.

Scars occurring in the neighbourhood of the secreting glands or the globe of the eye must be treated in such a way that damage does not occur to these structures.

The possibility of depilation of hair and eyebrows must be borne in mind when scars occur on the scalp or forehead.

So-called "Contact" therapy—that is low-voltage X-rays delivered at short focus skin distance—should always be employed in the treatment of abdominal scars in the female to avoid damage to the ovaries which might occur with more penetrating rays.

The use of other radiations such as U.V.L. to the areas where X-ray therapy is contemplated should be suspended, and the exposure of the part to strong summer sunlight should also be avoided.

Lastly it is important to consider the soil in which the lesion may be found, as the presence of arteriosclerosis, syphilis, diabetes or a poor blood supply due to damage to the main artery to the part affected may have impaired the tolerance of the tissues to the action of X-rays.

[November 14, 1945]

DISCUSSION ON THE CLINICAL IMPLICATIONS OF THE
DISABLED PERSONS (EMPLOYMENT) ACT, 1944

Dr. Harold Balme (*Medical Officer in charge of Rehabilitation, Ministry of Health*).—The Disabled Persons (Employment) Act, which came into law eighteen months ago, has not yet received the attention which it merits from the medical profession, and, so far as I know, this is the first occasion on which its clinical implications have been discussed by an official medical organization. And yet it will be obvious, from a study of the Act, that its provisions raise large issues in which the medical profession as a whole and the hospital services of the country in particular will be directly involved.

In general terms, the purposes of the Act may be summarized as follows:

First, it establishes the important principle that disability of any shape or form—whether congenital or acquired, medical or surgical, general or local—constitutes a claim upon the State for assistance, and that such assistance should not merely be expressed in terms of financial allowances or pensions, but rather in measures calculated to restore physical function, wherever possible, and reinstate the disabled person in some suitable form of gainful occupation.

Secondly, it makes provision for the vocational training and industrial resettlement of those who, subsequent to hospital treatment for injury or sickness, need to learn a new profession, trade or occupation before being fit to resume employment.

Thirdly, it assists disabled persons to secure work by means of a requirement on employers to engage a stated proportion of men or women so handicapped.

Fourthly, it provides employment under sheltered conditions for those who are severely disabled, but are able to do regular paid work provided that they do not have to stand up to the working conditions of competitive employment.

Such a programme may appear at first sight to constitute an industrial problem rather than a medical one, and to be more particularly concerned with the organization of suitable training courses and the finding of suitable jobs for the man or woman who, in the words of the Act, is "substantially handicapped in obtaining or keeping employment, or in undertaking work on his own account of a kind which, apart from that injury, disease or deformity, would be suited to his age, experience and qualifications". But it would be quite a mistake to regard this as being primarily an industrial question, for the ultimate success of this important measure of social legislation depends, in certain vital respects, on the active co-operation of the health services of this country, without which the real purpose of the Act will be frustrated. It is the purpose of this paper to suggest some of the lines along which such co-operation will be required, and to indicate means by which it can be effectively provided.

In the first place it will be noted that under the terms of the Act a Register is to be compiled of all persons substantially handicapped by reason of disability and whose disability is likely to last for a period of not less than six months, only children under working age and patients spending their whole time in hospitals or sanatoria being excluded from the list. This Register has already been opened, and it is estimated that by the time it is completed it will contain no less than a million to a million and a half names of people who will have the right to claim assistance in rehabilitation and industrial resettlement. The man with a spinal injury who can no longer work at the coal face in a stooping position; the patient with recurrent dermatitis of industrial origin; the man or woman who cannot stand excessive noise, or glare, or a dusty atmosphere; the man with limited movements of particular joints, or weakness of special muscular groups; the deaf and blind and limbless; the man with chronic peptic ulcer, who can only do regular work when hours are steady and opportunities for suitable diet available; and the chronic neurotic with his many varieties of psychosomatic disturbance—all of these, and many other groups, will qualify for admission to the Register. It is obvious, therefore, that it will be in the interests of all concerned—employers, employment exchanges and taxpayers alike—that their numbers should be kept to an irreducible minimum. This Register will not only be a record of disabled persons for whom suitable jobs must, if possible, be found; it will also be a register of the failure of our hospital services to prevent residual disability. It is obvious that in a large number of cases it is quite impossible to prevent such an end-result—we can hardly be held accountable for the congenital disabilities, at any rate!—but the health services of the future will be expected to do everything which lies in their power to limit the number of those who are left with disabilities which form a substantial handicap to the prosecution of their work.

In the second place, no scheme of vocational training, or of successful placement of disabled persons in industry, can ever succeed without medical guidance, particularly from those who actually treated the patients during their period of severe sickness or injury, and are able to assess the end-result in terms of loss of functional capacity. It is only by such assessment, expressed in terms that are easily interpreted by those upon whom will fall the task of finding new jobs or providing vocational training courses, that such disabled persons can be satisfactorily settled in fresh employment.

Thirdly, there will be need of very careful follow-up work and periodical review, in order to ascertain at the earliest possible moment if disabled persons are unable to stand up to the physical or psychological strain of the work which they have been advised to attempt, and require a further course of medical treatment or a transfer to some less strenuous form of occupation.

The particular directions, therefore, in which medical assistance is essential to the successful operation of this Act, may be summed up in the phrases: Prevention of residual disability; assessment of loss of functional capacity; and periodic follow-up and review. Let us now see how such assistance could be afforded, and what demands will be made on our future hospital and health services to provide the necessary facilities for medical rehabilitation, vocational guidance, and resettlement in suitable forms of industrial occupation.

MEDICAL REHABILITATION

The prevention of physical disability after severe accident or illness, by means of active forms of physiotherapy under expert guidance, has long been advocated by all experts in physical medicine, but it is only during this recent war that practical measures have been adopted, on any wide scale, to give expression to this purpose. The war has fostered the cause of medical rehabilitation in more ways than one. It has provided an overriding motive, in view of the urgent importance of getting Service men and women and essential war workers back to duty with as much speed and with as little residual disability as possible. It has made possible the erection and equipment of suitable rehabilitation departments in a large number of Service and E.M.S. Hospitals, and the appointment of the necessary staff of physiotherapists, physical training instructors and occupational therapists. And it has ensured the retention of patients in hospital or convalescent depot throughout the convalescent stage—at any rate, in the case of Service patients—thus making it possible to continue active measures of physical rehabilitation until the fullest measure of functional restoration has been obtained.

This development of rehabilitation facilities has not been confined to Service hospitals or to those special institutions which were taken over and up-graded by the E.M.S. for the reception of Service cases and air-raid casualties. It has since spread to a number of peacetime voluntary and local authority hospitals; at the present time there are approximately 350 civilian hospitals in the country, including those temporarily used by the E.M.S., which have established rehabilitation departments in greater or less degree. This encouraging result has been brought about by means of the special survey of rehabilitation facilities, organized by the E.M.S. in 1942 and carried out by experts in nearly 500 hospitals; the recommendations forwarded to hospital authorities arising from that survey; the special courses in rehabilitation technique organized and financed by the Ministry of Health at selected rehabilitation centres, and already attended by 254 doctors and 420 physiotherapists from 322 hospitals; and the practical assistance afforded to hospitals in the shape of equipment, gymnastic and sports apparatus, and improvised buildings.

The special conditions pertaining to wartime hospital practice, and the type of personnel which formed the majority of the patients for whom active rehabilitation has been provided, have necessarily been influential factors in shaping the programme of rehabilitation adopted at the most successful hospital centres, and many of these conditions will no longer exist in civilian hospital practice. Certain well-established principles have, however, emerged from this experience which should be of the greatest value in laying plans for the development of hospital rehabilitation as an integral part of our future health services and these may be summarized as follows:

(1) *Continuity of medical supervision.*—Rehabilitation is not to be regarded as something secondary to medical and surgical treatment, commenced and carried out during the period of convalescence. It is an essential part of treatment itself, and should therefore be prescribed by the physician or surgeon in charge of the case, who should maintain close supervision of the patient's progress both in the in-patient wards and out-patient department, and also, wherever possible, at the residential rehabilitation centre to which

the more severely disabled must be transferred for the final stages of their physical reconditioning, as described later in this paper.

(2) *Range of medical and surgical disabilities suitable for active rehabilitation.*—There is an unfortunate impression, widely prevalent, that active rehabilitation is only applicable to orthopaedic disabilities and traumatic surgery. This misapprehension largely derives from the historical fact that modern methods of physical rehabilitation sprang into popularity with the successful and brilliant work of Robert Jones and his orthopaedic colleagues during the war of 1914-18, and that the B.M.A. Committee on Fractures and the Delevingne Commission confined their recommendations to the setting up of rehabilitation departments in connexion with fracture clinics and the treatment of persons injured by accidents. The experience of this present war has proved that rehabilitation should not, and must not, be confined within such narrow limits, and that the same principles apply equally to all forms of medical and surgical disability or loss of physical and psychological function, resulting from prolonged immobilization or severe illness. Encouraging results have already been obtained by the scientific application of these principles to a variety of chest complaints, including chronic bronchitis and emphysema, asthma, pneumonia, empyema, and the after-treatment of lobectomy, pneumonectomy and thoracoplasty; to the recovery of abdominal muscular tone and the prevention of liability to hernia or prolapse after laparotomy or childbirth; to the rapid and complete recovery of the mobility of the fingers and hands after septic infections and burns; to the treatment of certain forms of arthritis which have reached a chronic stage, with a normal blood sedimentation rate; to the psychological readjustment of patients suffering from various manifestations of psychoneurosis; and to the partial or complete restoration of function after injury or disease of the central nervous system. In this last connexion, the brilliant results which have been obtained at Stoke Mandeville, in the treatment of spinal paraplegics under Dr. Guttmann's leadership, have proved convincingly that even so apparently hopeless a case as the patient with destruction of the spinal cord, and with complete loss of function of bladder and rectum and lower limbs, can yet be got on to his feet and enabled to take up useful forms of gainful occupation, as the result of a scientifically devised programme of thorough rehabilitation and vocational training.

(3) *Appointment of trained staff.*—The provision of an adequate hospital rehabilitation service in a hospital is not a matter which can be safely left to the haphazard device of any physiotherapist who happens to have been practising massage and electrotherapy there over a course of years. It is essentially a scientific form of treatment which is constantly changing and improving its technique, and can only be properly entrusted to a trained staff, thoroughly conversant with modern methods. At the head of such a staff there should obviously be, wherever possible, a specialist in physical medicine, to whom the actual superintendence of all forms of rehabilitation treatment should be delegated by the physician or surgeon in charge of the case, and who should have a free hand in ordering the particular forms of physiotherapy, physical exercises and occupational handicrafts best suited to each patient. In hospitals which have no physical medicine expert on the staff this duty is often entrusted to an orthopaedist, a surgeon in charge of the fracture clinic, or a resident medical or surgical officer, but it is an important principle, which war experience has abundantly confirmed, that this function should always be discharged by a single medical officer, who should be responsible for the training and general supervision of the various ancillary workers, and who should do everything possible to weld them into a united team.

Regular conferences on the problems presented by various types of disability, and the particular part which physiotherapy, group exercises, remedial games and occupational therapy severally play at each stage of recovery, are an important means of educating and uniting such a team, and should constitute one of the duties of such a rehabilitation medical officer.

(4) *A balanced and progressive programme.*—If rehabilitation is to be carried out scientifically and efficiently, it is essential that a carefully thought-out programme should be laid down for each type of medical and surgical disability and for each successive grade in the process of recovery. The basic principles underlying such a programme are fundamentally the same, whatever be the nature of the disability, combining as they do the use of physiotherapy and active exercises, remedial games and appropriate occupational handicrafts, alternating with prescribed periods of rest, relaxation and mental entertainment. The actual programme for each patient must, however, always be an individual matter, and must be related, not only to his particular illness or injury, but also to the type of work which he normally follows and to which he hopes to return. In the case of heavy manual workers, with reasonable expectation of being sufficiently restored to be able to resume their former occupation, it is obvious that the programme of rehabilita-

tion must be gradually stepped up, by means of strenuous exercises and heavy occupational handicrafts, until the patient is able to stand a muscular strain comparable to what he undergoes at work.

The initial stages of rehabilitation necessarily take place in the wards and out-patient department, for it cannot be too often emphasized that rehabilitation is not merely planned convalescence, as it is sometimes called, but is an integral part of medical and surgical treatment, and should commence as early as possible after the onset of illness or accident. All rehabilitation medical officers are agreed that their best results are obtained in cases which have been under supervision from the day of admission, and which have followed an appropriate programme from the first day on which it can be safely prescribed. It is the quadriceps and hamstrings drill given before and after cartilage operations, or after fractures of the lower limbs; the early abdominal exercises after laparotomy or childbirth; the early movements of fingers and hands after injuries and infections; and the special lower-thoracic and diaphragmatic breathing exercises given both before and after operation in the case of thoracic and upper abdominal surgery, which make for speedy recovery and help to prevent residual disability.

The later stages of rehabilitation, on the other hand, are best carried out, if possible, away from the hospital atmosphere. In the case of the more serious forms of disability, there is no question that the ideal method is by transfer to a residential rehabilitation centre, linked to the transferring hospital, so as to provide that continuity of medical supervision to which reference has already been made, but provided with ample facilities in the form of good playing fields, gymnasium, swimming pool and opportunity for the heavier handicrafts. For the minor forms of disability, every effort should be made to provide for the later stages of rehabilitation to be carried out in industry itself, and in those industrial concerns where a special rehabilitation workshop has been established—as at the Austin Motor Works, Vauxhall Motors, &c.—such patients are put on to the type of work which will provide the regular exercising of the particular muscle groups which are weak or the joints which are stiff, under the supervision of the industrial medical officer. In this way not only is the period of hospitalization materially shortened, but the patient has the added stimulus of being back on a money-earning job.

The important points which must be borne in mind in the preparation of a programme of rehabilitation, either in the early or late stages, are (a) that it must be well balanced; (b) that it must provide ample time for complete rest and relaxation; (c) that it must be progressive, increasing in content and in strenuousness as the patient begins to recover physical and mental vigour; (d) that it must provide for mental exercise and recreation, as well as physical; and (e) that it must always be related to the kind of work to which the patient hopes to return.

(5) *The care of the psychological factor.*—The experience which has been gained during the war at the special neurosis centres set up by the Service departments and by the E.M.S., and the valuable experimental work carried out at Roffey Park, have clearly proved the value of physical reconditioning, selected occupational handicrafts and group games as adjuncts to expert psychiatric treatment for patients suffering from psychoneurotic disorders. Apart, however, from patients in whom some definite form of neurosis is manifested, there is an element of psychological disturbance present in a great many cases of physical illness or injury, which can readily prove a serious deterrent to speedy recovery or satisfactory resettlement in industry. Anxiety about personal or domestic affairs, fear of losing one's job or becoming a permanent invalid, or opportunity to exaggerate symptoms as a means of escape from social obligations—all such factors may hinder successful rehabilitation unless wisely and sympathetically handled. It is here that the almoner or welfare worker, with her special training in social science and her long experience in dealing with individuals, can render such important service. If rehabilitation is to constitute an integral part of the future hospital services of the country, it is obvious that the almoner's department must be strengthened in every hospital (or speedily established, if not already in existence) and that these social workers must be set free from much of the routine financial work which at present absorbs so much of their time. It is only by sympathetic understanding of a patient's circumstances that his confidence can be won, his co-operation in his own recovery secured, and he can be guided back to a useful place in society.

ASSESSMENT OF FUNCTIONAL CAPACITY

There is a further duty which is laid upon our hospital services, in helping to implement the Disabled Persons (Employment) Act, namely the provision of scientific guidance as to the exact functional capacity of any patient who is disabled by reason of his illness or injury and will never be able to return to his former occupation. The actual responsi-

the more severely disabled must be transferred for the final stages of their physical reconditioning, as described later in this paper.

(2) *Range of medical and surgical disabilities suitable for active rehabilitation.*—There is an unfortunate impression, widely prevalent, that active rehabilitation is only applicable to orthopaedic disabilities and traumatic surgery. This misapprehension largely derives from the historical fact that modern methods of physical rehabilitation sprang into popularity with the successful and brilliant work of Robert Jones and his orthopaedic colleagues during the war of 1914-18, and that the B.M.A. Committee on Fractures and the Delevingne Commission confined their recommendations to the setting up of rehabilitation departments in connexion with fracture clinics and the treatment of persons injured by accidents. The experience of this present war has proved that rehabilitation should not, and must not, be confined within such narrow limits, and that the same principles apply equally to all forms of medical and surgical disability or loss of physical and psychological function, resulting from prolonged immobilization or severe illness. Encouraging results have already been obtained by the scientific application of these principles to a variety of chest complaints, including chronic bronchitis and emphysema, asthma, pneumonia, empyema, and the after-treatment of lobectomy, pneumonectomy and thoracoplasty; to the recovery of abdominal muscular tone and the prevention of liability to hernia or prolapse after laparotomy or childbirth; to the rapid and complete recovery of the mobility of the fingers and hands after septic infections and burns; to the treatment of certain forms of arthritis which have reached a chronic stage, with a normal blood sedimentation rate; to the psychological readjustment of patients suffering from various manifestations of psychoneurosis; and to the partial or complete restoration of function after injury or disease of the central nervous system. In this last connexion, the brilliant results which have been obtained at Stoke Mandeville, in the treatment of spinal paraplegics under Dr. Guttman's leadership, have proved convincingly that even so apparently hopeless a case as the patient with destruction of the spinal cord, and with complete loss of function of bladder and rectum and lower limbs, can yet be got on to his feet and enabled to take up useful forms of gainful occupation, as the result of a scientifically devised programme of thorough rehabilitation and vocational training.

(3) *Appointment of trained staff.*—The provision of an adequate hospital rehabilitation service in a hospital is not a matter which can be safely left to the haphazard device of any physiotherapist who happens to have been practising massage and electrotherapy there over a course of years. It is essentially a scientific form of treatment which is constantly changing and improving its technique, and can only be properly entrusted to a trained staff, thoroughly conversant with modern methods. At the head of such a staff there should obviously be, wherever possible, a specialist in physical medicine, to whom the actual superintendence of all forms of rehabilitation treatment should be delegated by the physician or surgeon in charge of the case, and who should have a free hand in ordering the particular forms of physiotherapy, physical exercises and occupational handicrafts best suited to each patient. In hospitals which have no physical medicine expert on the staff this duty is often entrusted to an orthopaedist, a surgeon in charge of the fracture clinic, or a resident medical or surgical officer, but it is an important principle, which war experience has abundantly confirmed, that this function should always be discharged by a single medical officer, who should be responsible for the training and general supervision of the various ancillary workers, and who should do everything possible to weld them into a united team.

Regular conferences on the problems presented by various types of disability, and the particular part which physiotherapy, group exercises, remedial games and occupational therapy severally play at each stage of recovery, are an important means of educating and uniting such a team, and should constitute one of the duties of such a rehabilitation medical officer.

(4) *A balanced and progressive programme.*—If rehabilitation is to be carried out scientifically and efficiently, it is essential that a carefully thought-out programme should be laid down for each type of medical and surgical disability and for each successive grade in the process of recovery. The basic principles underlying such a programme are fundamentally the same, whatever be the nature of the disability, combining as they do the use of physiotherapy and active exercises, remedial games and appropriate occupational handicrafts, alternating with prescribed periods of rest, relaxation and mental entertainment. The actual programme for each patient must, however, always be an individual matter, and must be related, not only to his particular illness or injury, but also to the type of work which he normally follows and to which he hopes to return. In the case of heavy manual workers, with reasonable expectation of being sufficiently restored to be able to resume their former occupation, it is obvious that the programme of rehabilita-

what is done in the hospitals in the form of medical rehabilitation. Successful rehabilitation needs a full partnership of patient, doctor and employer. The House may be surprised to know that more than 11,000 patients in Emergency Medical Service hospitals are now taking daily courses of remedial exercises in the wards. In addition, a further 20,000 attend the hospital gymnasium daily for special exercises and remedial games. Of these 31,000 receiving daily rehabilitation, 15,000 are also taking part in some form of occupational therapy. I think the House will agree that these figures are an impressive indication of the large measure of progress which is being made. Since my department made a special survey, in 1943, with the object of extending these facilities, the number of hospitals providing rehabilitation for their patients has increased from 150 to over 300. The great majority of Service sick and wounded received their medical rehabilitation in E.M.S. hospitals. More than 250 doctors have been given special courses of training, and for hospitals handicapped by lack of accommodation—a very serious difficulty—the Ministry have provided 34 pre-fabricated buildings. Conferences have been held throughout the country for leaders of industry, personnel managers, welfare officers and industrial medical officers, to explain the whole process of rehabilitation, and the part which industry has to play in the resettlement of patients.

Most of the cases to which I am referring concern wounded men, but there are also many surgical and other conditions where the rehabilitation we have in mind, as forming an essential part of the health services of the future, must be included. We shall not relax in this matter. The Ministry of Health will retain their rehabilitation department, and we shall endeavour to encourage rehabilitation as an integral part of the health services of the country."

We have yet to see how far this forecast will actually be reflected in the terms of the new Health Bill, but there is no reason to suppose that rehabilitation will be omitted from the provisions of that Bill. The necessity of providing facilities for hospital rehabilitation by the Ministry of Health is also specifically referred to in the White Paper which forms the basis of the Industrial Injuries Bill now before Parliament. It will obviously take some years before the necessary buildings and staff will be available for the carrying out of such a comprehensive scheme, but it is becoming increasingly clear that it will involve the provision of four types of medical rehabilitation centres:

(a) An efficient physiotherapy department at every hospital, with adequate accommodation, special equipment and trained staff, sufficient to give proper rehabilitation to all its in-patients. This should be a minimum requirement everywhere, and no hospital should be allowed to treat patients insured under the new health service which could not provide these facilities.

(b) A large out-patient rehabilitation centre (or centres) in every town or district, capable of receiving and treating patients attending the casualty or out-patient departments of the local hospitals who need daily rehabilitation to hasten recovery; former in-patients of the local hospitals who have been discharged from the wards owing to pressure of bed-space before being fit to return to full work; and non-hospital patients, referred by private and panel doctors and by industrial medical officers. Such out-patient centres would normally be situated at one or more of the local hospitals, where adequate accommodation was available; or could be set up by the joint action of more than one hospital; or could take the form of combined health and rehabilitation centres, under the health authority, drawing their expert staff from the consultants of adjacent hospitals.

(c) Residential rehabilitation centres, outside the town, to which all patients requiring long-stay rehabilitation could be transferred for the purpose from the hospitals in the neighbourhood.

(d) Special rehabilitation centres, scattered throughout the country, for the rehabilitation of particular disabilities. These would naturally include the orthopaedic hospitals for children; sanatoria and colonies for patients with pulmonary tuberculosis; centres for psychoneurotics; medical training centres for epileptics; centres with special "hardening" courses for sick or injured workmen from the heavier industries, such as mining and dock labouring; and other centres which will be required in connexion with experimental research in rehabilitation methods for special types of disability such as chronic cardiac cases, spastic paraplegics, chronic skin complaints, arthritis, &c.

It is obvious that the carrying out of such a programme will require a great expansion of trained staff. Many more specialists in physical medicine will be urgently needed, to give direction to medical rehabilitation at these various centres, and it is much to be hoped that many new recruits will be forthcoming from the ranks of medical officers who have taken an active part in physical medicine and rehabilitation whilst serving with the forces. An increased supply of physiotherapists and occupational therapists, almoners and social workers will be needed, including—it is hoped—male occupational therapists trained to supervise the heavier handicrafts and the operation of curative workshops. Physical training instructors and instructresses will both be required, and as a partial solution of that particular problem the Ministries of Health and Labour are now providing an intensive six-months' course in medical rehabilitation for selected P.T. instructors released from the forces, of whom 150 should be available in the course of the next twelve

bility of finding suitable work for such a man—if, indeed, such be possible—or of recommending a suitable course of training for some new vocation, rests upon the Disablement Rehabilitation Officer now attached to all the larger employment exchanges. But the D.R.O., as he is commonly called, has no knowledge of medicine or surgery, nor any previous experience of hospital practice, and must work completely in the dark unless carefully instructed and guided by those who have direct knowledge of the patient's physical condition and the extent and character of his disability. What the resettlement officers require to have at their disposal is a clear report stating, in simple physiological language, just what the disabled person can and cannot do, and what environmental conditions would be prejudicial to his health or likely to cause breakdown at work. Such a report can be supplied in the form of a medical certificate, such as the special D.P.I Form which has been issued experimentally by the Ministry of Labour, and which has been drawn up in such a way that every type of disability can be described in terms of functional capacity. But the ideal method of providing medical guidance in the resettlement of the disabled is not by certificate, but by regular conference between representatives of the hospital and of the employment exchange. I have recently seen what I regard as a model system at a large Local Authority hospital near London. At this hospital all cases requiring rehabilitation are referred by the physicians and surgeons to the specialist in physical medicine, who directs their programme of activities, and who has been provided with his own almoner for dealing with the personal, domestic and economic problems of each patient. A conference is held weekly by this medical director of rehabilitation, the almoner and the local D.R.O., when each patient likely to require vocational training for some new occupation is brought under review, and explicit recommendations as to suitable work are thus based upon the medical officer's intimate knowledge of the man's disability and functional capacity, the almoner's knowledge of his domestic and financial position, and the D.R.O.'s knowledge of available jobs, or possible courses of vocational training.

Periodic follow-up and review.—Once the disabled person ceases hospital treatment he becomes the responsibility of the Ministry of Labour, whose officers, aided and guided by the medical reports and recommendations above referred to, have to try to find suitable employment, appropriate to his reduced capacity or loss of particular function. In some cases this is merely a matter of looking for a vacant post in which the disability will not prove a handicap, e.g. a sitting job for a man or woman who can no longer stand at work all day, or work in an air-conditioned factory for the patient with chronic chest trouble. In other cases, however, it will involve a preliminary course at a training centre, in order to be fitted for some quite new occupation, or the provision of employment at one of the sheltered workshops which are to be established under the Act.

But whatever the route by which the disabled person reaches suitable occupation, his successful performance of his new task will depend upon his being able to stand up to the physical or nervous strain which it entails; and if wrong placement is to be quickly spotted, and cases of undue strain speedily relieved, careful supervision and periodic review are essential. In many cases this supervision will be maintained by an industrial medical officer or personnel manager, if the patient happens to be working in a large industrial organization provided with such officers. The employment exchanges will also be interested in following up the results of their placements in industry. But rehabilitation is primarily a medical problem, not an industrial one, and it is the hospital which actually treated the patient and saw him through to the point at which he was to be fitted out for a new job, which always ought to take the initiative in following up its cases, and arranging for a return to hospital and careful review of every case in which there is any doubt of ability to make the grade.

THE FUTURE OF HOSPITAL REHABILITATION

The foregoing consideration of the clinical implications of the Disabled Persons (Employment) Act should make it clear that for the successful implementation of the Act, the setting up of a comprehensive system of hospital rehabilitation will be needed throughout the country. But this is not the only reason for anticipating a great expansion of rehabilitation facilities in the future. The White Paper on National Health Service specifically mentioned rehabilitation as one of the medical benefits which should be covered by the health insurance scheme and which insured persons would therefore have a right to claim, and in his last report to the House of Commons on June 12, 1945, the former Minister of Health, Mr. Willink, made the following important reference to the subject:

"I should like to say something about rehabilitation, because I do not think it is generally realized how much this has been developed during the war in hospitals within the Emergency Medical Service. The House has been concerned, through legislation introduced by the Minister of Labour, with the great question of industrial legislation and resettlement, but, of course, everything that is done in this field must depend upon

Concerning the fuller development of a policy to link hospitals with industry the Act has little to say; it is suggested (by the writer) that this should become a responsibility of District Advisory Committees.¹ The D.R.O. is the present link, but so far—for reasons out-with his control very often—the system has not been a success. This fact is one which the National Advisory Council¹ must face up to, and if necessary provide an alternative remedy. Hospital authorities may therefore have to consider the possibility of appointing their own industrial liaison officers—persons with practical experience of factory work, but not necessarily with medical or nursing qualifications—who would not only provide a link with the patient's employer but advise the surgeon concerning job-allocation in relation to the physical and mental requirements of different occupations. How many physicians or surgeons, for example, have ever seen a man operating a capstan lathe or a hydraulic hammer, or know the work of a moulder in an iron foundry?

THE CONTRIBUTION OF INDUSTRIAL MANAGEMENT

No matter how efficient the hospital, how good the treatment, and how much contact the social service or almoner's department has with the factory there can be no effective return to work, and therefore no full rehabilitation and implementation of the Act, without the co-operation of the employer. His contribution must include the following:

(a) The promise of continued employment can remove the fear of insecurity, a potent means of retarding recovery. It is a fact that many disabled workers already in employment are unwilling to put their names on the Register of Disabled Persons because of the fear of losing their job. Some statement from employers' organizations may therefore be necessary at an early date.

(b) A promise of alternative work can be made if the employee is unfit for his pre-accident job. To be effective this must be true alternative work under medical supervision and not light work specially created as a charity.

(c) The possibility of re-training for alternative work should be considered. This can only be done in the larger firms; Government Training Centres and certain extra-industrial centres can theoretically cover the remainder of industry.

(d) Assistance on matters arising under the Workmen's Compensation Acts is important. The present Acts, although financially more attractive within recent years, can still do much to retard recovery particularly in long-continuing cases by creating distrust of the employer on the part of the worker. Some insurance companies have contributed in no small way to this. But even with the new Industrial Injuries Act there will be much help required from management. The employer's fear of the consequences of yet another Government department coming into the day-to-day routine of industry is very real; not only can this still further widen the gap between employees and employers, but by its very cumbersomeness cause irksome delays and difficulties. So there is real need to provide some human link between the Ministry of National Insurance, the Ministry of Labour, and industry.

(e) It is important that employers should appreciate the fact that a man cannot be unfit one day and on the next, in a different environment, be really fit for full work. The goodwill of managers and foremen (the real executives of industry) must therefore be obtained for the worker during what is often an awkward phase in recovery—that period of time between being signed off by the insurance practitioner or the hospital and returning to his original occupation.

(f) The provision of rehabilitation workshops in the larger organizations, e.g. every factory or group employing 5,000 workers or more (to include medical as well as surgical cases), or on a regional basis by the institution of communal rehabilitation factories linked with hospitals,² must be fully considered.

Personnel management and rehabilitation.—It should be a primary responsibility of personnel management, under the present system, to play a part in the supervision of the return to work of the sick or injured worker. This applies to all types of industry, and to all sizes of organization. In the larger firms personnel management and industrial medical service must work in the closest collaboration. One cannot function efficiently without the other. In the smaller industrial unit, e.g. the factory with less than 300-400 employees, there is usually no special official appointed as personnel or welfare officer and this function therefore becomes the direct responsibility of the works manager. Because the majority of firms in this country come within the "small" category, and

¹ See Disabled Persons (Employment) Act, p. 10.

² A scheme for communal rehabilitation workshops has been planned for Birmingham and will be published at a later date by Mr. W. Gissane and the writer.

months. But the greatest need of all will be the inclusion of regular instruction in rehabilitation as part of the ordinary medical curriculum, and the integration of this important development in social medicine in the education of all future members of the medical profession.

Dr. Donald Stewart, Birmingham: Industrial rehabilitation.—Section 3 of the Disabled Persons (Employment) Act, 1944, promises facilities for "industrial rehabilitation courses". It lays down that these will be for disabled persons over 16 years of age who are unfit because of injury, disease, or deformity and who need such facilities to render them fit for their previous work. At these courses, according to the Act, will be provided (a) physical training and exercise, (b) occupations conducive to restoration of fitness, and (c) other incidental facilities—all to be under adequate medical supervision. Where exactly the courses are to be held is not yet known, but if special centres are set up for the purpose the expense to the country must be fully justified. Physical training and exercise can be adequately provided at hospitals and at rehabilitation centres. Occupations "conducive to restoration of fitness" can be provided on a small and relatively unimportant scale in rehabilitation centres (although this needs further expert advice and planning) and in sheltered environment such as that already provided for cases of tuberculosis; but, most important of all, they can be provided, and provided well, in normal industry and in special rehabilitation shops and factories.

The implementation of the recommendation in the Act which states that all this is to be under medical supervision is of special significance and needs emphasis. Rehabilitation is an essential part of treatment and to be successful it must, in all its stages, be under medical control. That phase which is now termed industrial rehabilitation, therefore, must also come under medical care until the patient is fit for his pre-accident or pre-sickness employment, or has been satisfactorily trained for other work. This is a challenge to medicine from the workpeople of this country which must be fully understood and accepted by those responsible for planning the new national health service. Present facilities in industry for rehabilitation under medical supervision are to be found only in those firms that have developed their own medical service, and from present practice in industrial medicine much can be learnt concerning the clinical implementation of the new Act. Conversely, the future development of industrial rehabilitation, and this includes its interpretation under the Act, must be accompanied by medical supervision at the place of work, that is, by a comprehensive industrial health service. Without this the new legislation cannot be fully implemented from the clinical point of view and will largely fail—in spite of the elaborate machinery that has been set up.

HOSPITALS AND INDUSTRY

Hospital services deal in the main with anatomical and functional recovery. Many of them are now venturing into the social field by changing the outlook and work of the almoner. But the new aim of rehabilitation must be to base it on economic grounds, where the man obtains at the earliest possible opportunity—it may be during treatment—both work and reward; national benefits are only palliative and, under the present system of workmen's compensation or even the new Industrial Injuries Act soon to become law, may actually retard recovery.

Three points relevant to hospitals have a bearing on the industrial side of the problem: (a) With good treatment the need for special rehabilitation measures decreases. Industry is therefore fundamentally interested in the future hospital policy of this country on purely economic grounds. (b) There is a grave risk that "rehabilitation" may be plugged too hard (using the word in the narrower sense) at the expense of earning capacity. Ancillary aids to cure such as occupational therapy may possibly be overdone because they are new to the public (and this includes politicians) and somewhat dramatic. Hospitals may have purchased expensive equipment (e.g. weaving looms) and appointed considerable staff (e.g. physiotherapists and occupational therapists) and it is only natural to provide sufficient patients to fill the department and attempt to justify expenditure. There may also be insufficient strictness of control of the various stages of recovery by physicians and surgeons themselves, who can place too much therapeutic reliance on basketry, weaving, or the manufacture of dog-leads. (c) The policy of setting up social service departments in hospitals is gradually providing an important link with industry. The function of the almoner is changing, and her contact with management on behalf of the sick and injured worker is a real advance in hospital service. On the other hand, industry itself frequently needs contact with hospitals: it must have knowledge of progress of key men for instance, or it may wish to offer special facilities to an injured man to aid his recovery.

determine what types of individual, both healthy and disabled, should be allocated to each job. Factors in job-allocation are age, sex, general physical and mental make-up, arm and leg efficiency, hearing, vision, and general stability, i.e. a simple adaptation of the Pulhems system used in the Services.

(g) He should consider the advisability of having a social service worker on his own staff. This has already been accepted in principle by certain large firms and is a development of some importance in industrial medicine.

(h) The whole-time industrial medical officer should investigate the possibility of setting up a special workshop in his own organization for the rehabilitation of selected sick and injured workers. Selection should be made in full collaboration with hospital physicians and surgeons, who should act in a consultative capacity in this respect and so themselves learn something of industrial conditions. The potential medical contribution to industrial rehabilitation is thus great, particularly in our larger cities. This type of workshop provides one good answer to the problem of rehabilitation and it should essentially develop as a part of industrial medical service. The Austin experiment is an example of this and a brief account of the scheme is given below.

THE AUSTIN EXPERIMENT

A special rehabilitation shop has been set up at a large engineering works in Birmingham (the Austin Motor Company) for injured employees who normally would not be at work, but would be undergoing treatment. The scheme came into being in April 1943, and was primarily organized by the writer as consulting medical officer to the firm, in collaboration with Mr. W. Gissane, surgeon-in-chief, Birmingham Accident Hospital. (This scheme is similar in some ways to those developed by certain Royal Ordnance Factories during the late war, and to the scheme evolved by Mr. A. H. McIndoe and Mr. George Reid for R.A.F. casualties at East Grinstead.)

The demand.—During the war this firm employed 30,000 workers and had over 1,000 "reportable" accidents annually, i.e. that lose three days or more. By spot surveys it was assumed that at any one time, i.e. on any one working day in the year, some 30 to 40 injured workers could be given "alternative" work in the Shop during the period of treatment, and this assumption has proved to be reasonably correct. The average number in the Shop during the past two and a half years has been 30 to 35. It is interesting that even although the number of persons employed and the number of accidents have decreased since the war ended, the Shop is still kept busy and full.

The link with treatment.—Under medical supervision this work has a definite therapeutic value, and comes within that part of rehabilitation already termed occupational therapy. An essential part of the experiment has been that the surgeons of the Birmingham Accident Hospital act in an advisory capacity to the firm's medical officer on the clinical side of the work, including selection of cases, selection of occupation, follow-up, and progression in occupation until the "patient" is fit for his pre-accident work, or is fully retrained for other work in the factory. Thus a partnership between hospital and industry has been created. The following cases illustrate the value of the Shop.

(1) *Example of occupational therapy and progression from job to job.*—A man has a simple fracture of the left radius and ulna. It is not necessary for him to be treated as an in-patient at hospital so he attends regularly at the out-patient department. Even by the best treatment and rehabilitation methods it will be fourteen weeks before he is normally fit for work. Such a case can be admitted to the Shop in seven days, given at first a one-handed job, then a job where he needs slight movement in the injured part, and gradually progressed through the Shop until he has full function.

(2) *Alternative work for patients awaiting treatment, who would normally be unemployed.*—A girl sustains an extensive laceration of the muscles of the right leg and foot. She has treatment in hospital as an in-patient for ten weeks. This period cannot possibly be cut down. It is then found that to give her a good foot again she must have a plastic repair. The surgeon decides that this cannot be done for at least three months until her tissues regain their vitality. Normally this girl would be out of work during that period. She is admitted to the Shop and three months' work is saved.

(3) *Retraining of permanent cripples.*—A pre-war tailor, employed as a machine operator, loses all the fingers of his right hand in his machine. He is successfully treated by the surgeon, but to all intents and purposes is a one-handed man thereafter. He will be unable to become a tailor again, and is not unnaturally afraid to work on moving machinery. His confidence has gone, and he develops an anxiety state. He is eventually persuaded to enter the Shop and is given bench work such as filing, frazing and scraping, and so he is gradually re-educated to a confidence in the use of machinery which will enable him to be fully retrained as an effective machine worker.

The Shop.—The Rehabilitation Shop is situated near a main gate of the works and near the canteen. From the industrial hygiene point of view working conditions are good, e.g. lighting, heating, ventilation, clothing accommodation, colour schemes, sanitary

because over 50% of factory workers (comprising 75% of productive industry) are employed in units of 250 or less, the education of works managers and foremen in the meaning of rehabilitation, and the part they must play in it, becomes increasingly important.

Light work or alternative work.—A number of firms have appreciated the need for "light" or "alternative" work and have provided facilities within their own limitations; but there is no doubt that the finding of such work is a matter of considerable difficulty taking industry as a whole, and in the small organization is frequently impossible. In certain large firms, however, a number of occupations are specially allocated for convalescent sick and injured patients as part of general welfare schemes. The main criticism of this procedure is that cases are often not under adequate medical control, and that this "allocation" becomes a method of dumping and "losing" unwanted workers often to reduce the so-called "compensation costs".

Objections to alternative or light work can be summed up as follows: (a) It is frequently hit-or-miss therapy; (b) it is difficult to find in the great majority of industries; (c) it is difficult to keep under medical control, and may actually be harmful to the patient by retarding or even permanently interfering with full functional activity; (d) it is frequently not liked by managers, foremen, and by workers themselves, as the productive effort of the industrial unit—the gang or team—may be interfered with by the presence of a semi-fit man; (e) managers and foremen may resent the increase in overhead expenses; (f) the patient is apt to be "lost" in the works and frequently never returns to his pre-accident work; alternative work, therefore, can conceivably become nothing more or less than a scrap-heap for the partially disabled man; (g) it is sometimes created at the special request of the insurance company concerned, where lump sum settlements are involved, as a basis of argument in the County Court in favour of lower settlement.

THE CONTRIBUTION OF INDUSTRIAL MEDICINE

In firms where an industrial medical officer is employed supervision of return to work of the injured or sick worker is one of his primary duties. So important is this work that it is a main reason for the extension of medical services to cover the whole of industry. He can contribute to the clinical implementation of the Act in a number of ways:

(a) He should obtain accurate information not only of the incidence of sickness and accidents but of the progress of all sick and injured workers. The value of a good record-keeping system is therefore emphasized.

(b) He should devise a method of reviewing progress, as required, with hospital staffs and with insurance practitioners. To this review his special knowledge of the work to which the sick or injured worker will return is a valuable contribution; his advice may only be useful in a proportion of cases to begin with, but the number will grow. He should look on the local hospital as his base; medical departments in industry should become outposts of hospitals and not work in isolation.

(c) All accident cases absent for three days or more should be seen by him before recommencing work.

(d) All sickness cases absent three weeks or more should be seen by him before recommencing work. To carry this out effectively he should establish close liaison with local general practitioners. Later this can be done through health centres.

(e) He should develop an adequate follow-up service in connexion with (c) and (d), and in this part of his work the help of a good nurse is of much importance.

(f) He should compile a list of the different occupations in his firm, analysing jobs from the health point of view and in relation to capacity for work, with a view to providing alternative work for specially selected cases conditional on their being under his medical supervision. It must be clearly stated that the doctor's contribution to this is one of job-allocation and is dependent on a job-analysis schedule being provided by industry. This development in medicine is therefore a two-way process, and depends for its success on collaboration between management and the medical officer.

For instance in the iron foundry to-day are to be found the following occupations: annealing, casting, core-making, clerical work, crane-driving, cupola work, dressing (fettling, grinding, trimming, knock-out work), labouring (heavy, medium and light), maintenance (skilled engineering, millwrights), moulding (hand, machine), shot-blasting, truck-driving, viewing (inspecting), and welding. Job analysis of each of these occupations should be carried out by the management, and the results given to the medical officer. It then becomes his responsibility to

SUMMARY

Industrial rehabilitation is necessary for the full clinical implementation of the Disabled Persons (Employment) Act. The Act apparently allows for this to be under medical supervision.

Industrial rehabilitation can be carried out at special centres, in hospitals and rehabilitation centres, but best of all in rehabilitation workshops and in normal industry.

At the present time industrial medicine is attempting to carry out industrial rehabilitation, and some account of this work is given. Without a properly organized and comprehensive industrial health service to cover all workers industrial rehabilitation will not be fully possible, nor can the Act be fully implemented.

Mr. H. Ernest Griffiths: Dr. Balme, in discussing the provisions of the Disabled Persons Act, gave a figure of upwards of a million as a possible number who might appear upon the Register. This figure was certainly conservative and might indeed reach three millions.

But no mention has been made as to what the Act would cost industry if rehabilitation in its fullest sense were not achieved. It would mean that say $1\frac{1}{2}$ million people would have to be found selected and unproductive jobs at a cost to their employers of some three hundred million pounds a year for "liftmen and lavatory attendants".

Dr. Balme told us that the Ministry of Labour had introduced a form, the D.P.1, which when filled in by the doctor, would give the D.R.O. a functional analysis of the patient's ability to perform the manoeuvres of work. Dr. Stewart told us that the job analysis had not been accomplished but that he thought that it would be a relatively simple item. On this latter point I venture to disagree.

An empirical job analysis can certainly be made by the motion engineer or by any observant foreman, but this form of analysis will be of little value in the placing of the disabled. For this, a functional job analysis based on physiological principles with its wealth of the possibility of employment of alternative function is essential. This research work will require highly specialized teams and, until it is completed, the Disabled Persons Act must fall short of expectations.

Very interesting slides of the rehabilitation workshops at the Austin Works emphasized the value of this phase in treatment. In my own opinion the rehabilitation workshop has a greater educational value than a curative value. In those shops both doctor and labour managers learn much of the physiology of job analysis and of the capacity for work of their patients. Whereas certain special cases will always require a rehabilitation workshop for their quickest and best rehabilitation, the majority of cases will do better on alternative work within the industry.

Dr. John Agate: In spite of the optimism so far shown, the working of the Act gives some cause for alarm. If between 1 and 2 million disabled persons are going to register notice must be taken of the Ministry of Labour's own estimate that, of these, 25% have "surgical" disabilities, 50% have "medical" disabilities, and 25% are neurotic. The earlier speakers have in fact referred principally to the handling of the 25% of surgical cases. Most of the remainder can only be improved a little by treatment and physical medicine, and they tend to deteriorate slowly or reach a stationary condition. All such treatment is nullified unless each individual can finally be placed in the right job. Here is a very weak point in the system which is now operating, namely the Disablement Rehabilitation Officer (D.R.O.). In practice these officers do not seem to be satisfactorily handling the problem. As an experiment in a certain cardiac clinic some 300 cases in eighteen months were followed up and at the moment only two-fifths have been satisfactorily placed despite the energetic efforts of physicians and a lady almoner. The initiative was in most cases taken by them and the D.R.O.'s contribution to the number of successes was small.

In many medical disabilities it is dyspnoea on exertion that is the main handicap and determines the kind of work a man can do. Cardiac cases prove hard to place. Ideally, each should be placed individually in work through the efforts of a team of doctors and almoners based on a cardiac clinic and advising the officers of the local labour exchange. But this method is extremely time-consuming, and there can probably never be enough suitably trained staff in the country. The alternative might be to provide a directive to labour exchange officers so that given disabilities and occupations can be matched. So an attempt is being made to go into the factories, peruse the medical records, assess the cardiac cases so found, and visit them at their jobs. This has proved even more time-consuming. It takes over two hours' work for every case one finds, and

conveniences, washing facilities, seating facilities, and rest pauses. The "hours of work" are 8 a.m. to 5.30 p.m., and 8 a.m. to 12 noon on Saturdays. The lay-out of the Shop was designed by the Production Director of the firm, and the machinery installed is of a modern type, e.g. no overhead belting. The importance of adapting the plant and machinery to the needs of the injured limb was specially considered by the firm's medical advisers, the Accident Hospital staff, and the management.

Occupations suitable for crippled workers, e.g. with one arm, hand or leg out of action were selected as follows:

Hand and automatic milling.
Drilling of all types.
Capstan work.
General centre lathe turning.
Spot welding, worked by either hand or foot.
Lining. (This can be done with either hand.)
Fly presses.
Electric arc welding. (This for a one-armed man.)
Automatic screwing.
Surface grinding.
Soft soldering.
High pressure gas welding.
Bench work including: Filing; hand dyeing; counter sinking; fraizing; scraping; assembling; hand pressing.

Examples of products manufactured in the Shop are:

Oil strainers for all engines produced by the firm.
Starter nuts for all engines produced by the firm.
Spring pins.
Brake levers.
Bolts of different types.
Work trays.
Barrel nipples for oil pipes.

Management of the Shop.—A trained and experienced engineer was appointed to be the Shop manager. Before commencing work he was given an opportunity to appreciate the surgical, social and economic background of the accident problem as it exists in this country, and with this in view visited different rehabilitation centres and hospitals. It was considered that this appointment was of vital importance in the experiment, as any success that might be obtained would in a large measure be due to his personal efforts. After two and a half years' work this has proved to be the case and those of us connected in any way with the experiment must pay tribute to the way in which he has carried out his work.

Payment and incentives.—A payment method known as the "2-4-6 system" has been used. If a man receives say £2 a week on compensation and his average pre-accident earnings are £6 a week, it was proposed that his payment in the Shop should be not less than £4 per week. This means that he has a double incentive: (a) to earn more than he would on compensation and so be attracted to work in the Shop; and (b) to strive towards his pre-accident rate. The man is only in the Shop during such time as he is certified for such work by the surgeon. He returns eventually to his pre-accident work, or to other full work for which he would be suitably trained, in other parts of the factory.

Examples of payments are as follows (as at July 1943):

	Pre-accident rate			Shop rate*		
	£	s.	d.	£	s.	d.
Case 1 (female aged 29)	4	17	9	3	16	6
Case 2 (female aged 17)	3	0	9	2	7	9
Case 3 (male aged 41)	6	14	6	5	8	6
Case 4 (male aged 16)	2	3	10	1	15	6
Case 5 (male aged 30)	7	15	2	5	14	6
Case 6 (male aged 56)	5	4	5	3	9	6

*The Shop rate is made up as follows: flat rate, plus cost-of-living bonus, plus any compensation for which he may be eligible under the Acts.

Results.—During the two and a half years of its existence the Shop has employed over 500 injured workers. The majority of these were patients of the Birmingham Accident Hospital. Approximately 80% of cases returned to their original work; 10% to a different job because of change of products of manufacture due to the ending of the war; 5% were retrained for other work; and 5% transferred to other work because of their disability, no special training being necessary.

SUMMARY

Industrial rehabilitation is necessary for the full clinical implementation of the Disabled Persons (Employment) Act. The Act apparently allows for this to be under medical supervision.

Industrial rehabilitation can be carried out at special centres, in hospitals and rehabilitation centres, but best of all in rehabilitation workshops and in normal industry.

At the present time industrial medicine is attempting to carry out industrial rehabilitation, and some account of this work is given. Without a properly organized and comprehensive industrial health service to cover all workers industrial rehabilitation will not be fully possible, nor can the Act be fully implemented.

Mr. H. Ernest Griffiths: Dr. Balme, in discussing the provisions of the Disabled Persons Act, gave a figure of upwards of a million as a possible number who might appear upon the Register. This figure was certainly conservative and might indeed reach three millions.

But no mention has been made as to what the Act would cost industry if rehabilitation in its fullest sense were not achieved. It would mean that say 1½ million people would have to be found selected and unproductive jobs at a cost to their employers of some three hundred million pounds a year for "liftmen and lavatory attendants".

Dr. Balme told us that the Ministry of Labour had introduced a form, the D.P.I., which when filled in by the doctor, would give the D.R.O. a functional analysis of the patient's ability to perform the manoeuvres of work. Dr. Stewart told us that the job analysis had not been accomplished but that he thought that it would be a relatively simple item. On this latter point I venture to disagree.

An empirical job analysis can certainly be made by the motion engineer or by any observant foreman, but this form of analysis will be of little value in the placing of the disabled. For this, a functional job analysis based on physiological principles with its wealth of the possibility of employment of alternative function is essential. This research work will require highly specialized teams and, until it is completed, the Disabled Persons Act must fall short of expectations.

Very interesting slides of the rehabilitation workshops at the Austin Works emphasized the value of this phase in treatment. In my own opinion the rehabilitation workshop has a greater educational value than a curative value. In those shops both doctor and labour managers learn much of the physiology of job analysis and of the capacity for work of their patients. Whereas certain special cases will always require a rehabilitation workshop for their quickest and best rehabilitation, the majority of cases will do better on alternative work within the industry.

Dr. John Agate: In spite of the optimism so far shown, the working of the Act gives some cause for alarm. If between 1 and 2 million disabled persons are going to register notice must be taken of the Ministry of Labour's own estimate that, of these, 25% have "surgical" disabilities, 50% have "medical" disabilities, and 25% are neurotic. The earlier speakers have in fact referred principally to the handling of the 25% of surgical cases. Most of the remainder can only be improved a little by treatment and physical medicine, and they tend to deteriorate slowly or reach a stationary condition. All such treatment is nullified unless each individual can finally be placed in the right job. Here is a very weak point in the system which is now operating, namely the Disablement Rehabilitation Officer (D.R.O.). In practice these officers do not seem to be satisfactorily handling the problem. As an experiment in a certain cardiac clinic some 300 cases in eighteen months were followed up and at the moment only two-fifths have been satisfactorily placed despite the energetic efforts of physicians and a lady almoner. The initiative was in most cases taken by them and the D.R.O.'s contribution to the number of successes was small.

In many medical disabilities it is dyspnoea on exertion that is the main handicap and determines the kind of work a man can do. Cardiac cases prove hard to place. Ideally, each should be placed individually in work through the efforts of a team of doctors and almoners based on a cardiac clinic and advising the officers of the local labour exchange. But this method is extremely time-consuming, and there can probably never be enough suitably trained staff in the country. The alternative might be to provide a directive to labour exchange officers so that given disabilities and occupations can be matched. So an attempt is being made to go into the factories, peruse the medical records, assess the cardiac cases so found, and visit them at their jobs. This has proved even more time-consuming. It takes over two hours' work for every case one finds, and

the results are not statistically significant because of the thousands of possible jobs and degrees of cardiac disability. What is most needed for resettling disabled workers is a comprehensive job analysis for all occupations in the country. Apparently the Ministry of Labour is not tackling the problem itself, but is relying on the spasmodic efforts of individual firms. No real results are expected for five to ten years.

A possible alternative is for the doctor who knows the case of a disabled man to prohibit specifically certain physical actions, such as lifting weights of more than 20 lb. The new Ministry form "D.P.I." now in experimental use has this as its basis, it is very helpful, is easy to use, but is not yet approved by the B.M.A. and may not therefore come into general use. Much more must be learned by doctors and labour officials of the capabilities of the medically disabled and the physical requirements of industrial occupations.

Sir Reginald Watson-Jones was glad to have heard constructive criticism of the steps which had been taken to implement the Disabled Persons Employment Act because, as Chairman of the Medical Committee of the National Advisory Council, it was his duty to advise the Ministry of Labour and National Service and no one who applied his mind to these problems could believe that they were easy of solution. At an earlier stage the Ministry had been advised that disability analysis on the one hand and job analysis on the other were all that was necessary. But so simple an equation was impracticable. In most cases the resettlement of disabled persons called for very skilled medical experience coupled with a knowledge of industry. Disablement Rehabilitation Officers could be trained to appreciate the industrial problems, and special courses were being arranged by which to improve the service of a group of men and women who had done all that was possible during a period of acute man-power stringency. Nevertheless it was obvious that medical direction was also essential and the Ministry of Labour had now been advised that Disablement Rehabilitation Officers should be directed by local medical boards and their activities co-ordinated by regional medical consultants, so that disabled persons would be guided to the type of employment most suited to their disabilities. Every doctor who shared in treatment could make a valuable contribution. There was danger that the Act might fail by reason of the failure of disabled persons to register. Patients who had been well treated might reasonably hesitate to accept the label of "disabled"; and yet if they did not register the quota which gave them the right of employment would be misleading. Dr. Balme had indicated that there were probably from one to one and a half million disabled persons in this country; but at the present rate of registration many years would elapse before this number was on the register and the quota reliable. Doctors should so influence their patients that a complete record was available of every individual who might have difficulty in seeking or keeping employment. If this were *not* done one of the greatest medical and social reforms of this generation would be imperilled.

President—E. N. ALLOTT, F.R.C.P.

[December 11, 1945]

DISCUSSION ON D.D.T.

Professor G. R. Cameron opened the discussion. His paper was published by the British Council (*British Medical Bulletin*, 1945, 3, 233) and summarizes a much longer paper which appeared in the *British Medical Journal* of June 23, 1945, p. 865.

Dr. Herbert D. Chalke, late Colonel R.A.M.C.: My contribution is a brief account of the use of D.D.T. in the field during the Italian Campaign, particularly during the Naples typhus epidemic, and as an anti-malaria measure. All this has become ancient history, but you may be interested to hear something of the experiences and difficulties during the days when we were experimenting with an insecticide which was rather an unknown quantity.

The Naples typhus epidemic.—Naples when we occupied it in October 1943 was a very sad city, badly bombed, overcrowded, with a depressed and undernourished populace living in considerable numbers permanently in shelters. Below the streets of Naples and on the outskirts of the city are innumerable caves and tunnels, many dating back to ancient times. These were the permanent homes of thousands of people. Naples seemed to be the perfect stage setting for a large-scale epidemic of a disease such as typhoid or typhus. Means of heating and lighting were lacking, the water mains and sewers were ruptured, and a large proportion of the people were lousy. For example, the largest civil hospital housed almost a thousand patients, all said to be infested. The public services, including the public health and practitioner services were quite disorganized, despair and apathy ruled the land. Under these circumstances it was hopeless to expect any but the scantiest of infectious disease statistics. The Allied Military Government (A.M.G.) commenced to function at an early date, and their medical officers worked magnificently in trying to restore the medical services to normal. My main fear was of an outbreak of typhoid, but fortunately this did not occur in Naples, although other towns were severely affected. We were on the lookout for the occurrence of typhus cases, and on November 20 information was received that 7 cases had been reported in the city. A conference was called the next day and a committee appointed to investigate—it consisted of Allied and Italian medical officers. Clinical examination of the cases suggested that we were, indeed, dealing with classical typhus. Although at that time no information as to previous cases could be obtained from the Italian doctors, documents were brought to light at a later date that made it clear that sporadic cases had been occurring since March. It was said to have been introduced by Serbian Prisoners of War who were scattered throughout the city as a result of Allied bomb damage. Civilian cases occurred in July—a man visiting a bathing place used by troops, who returned home lousy, was the first case. Afterwards cases occurred in jails, but many prisoners—contacts—were said to have escaped and were not traced. The Allied Committee arranged for the setting up of disinfection and bathing centres, but all the principal disinfestors had been destroyed by bombing or enemy sabotage. Fuel and soap were almost unobtainable. Indeed, soap was extremely scarce throughout the epidemic, and the populace remained unwashed, in particular the 20,000 shelter inhabitants. Application was immediately made to higher Allied Authority for supplies of soap and insecticide powders.

Progress of the epidemic.—

November 17 to 30	36 cases
December 1 to 7	22 cases
December 8 to 14	45 cases
December 15 to 22	36 cases
December 23 to 28	138 cases

It was evident that a severe typhus outbreak was about to occur among the million inhabitants of Naples.

The situation was serious. Naples had a very large Allied troop population, and it was the main port of Italy, which it was vital to keep open during this critical stage of the Italian Campaign and the eve of the Anzio landings. Hygiene sections played an admirable part at this, and subsequent stages of the epidemic, in constructing baths, disinfection centres and improvised steam disinfestors, and in controlling the insecticide dusting of the 30,000 odd Italians employed in British messes, ordnance factories,

workshops, and on the docks. They also worked in collaboration with A.M.C. in dusting refugees and typhus contacts in the Army areas. Drs. Soper and Davis of the Rockefeller Foundation arrived in Naples early in December. Case searching, contact delousing and block dusting commenced at once under their direction.

Teams of trained civilians dusted shelter-dwellers. Brig. General Fox and the U.S. Typhus Commission commenced work early in January; a mass delousing scheme was rapidly organized and energetically pursued. Twelve public centres were soon functioning, inoculation was commenced, and propaganda increased. This work was handed over to the Allied Commission on February 19.

Drs. Soper and Davis, who did admirable work, used American Service "M.Y.L." insecticide by means of hand dust guns of the "Hudson Admiral" type. During this period only about 10% of the dustings were done with D.D.T. (10% in talc). 5,000 dustings (approx.) were carried out during this time, about 3,000 of them were on typhus contacts. The principle of mechanical dusting was quickly taken up by us, using AL 63 powder. Power units were also obtained from local garages and experimented with. The British Hygiene Services were responsible for the 30,000 civilians in their employ, and for the Italian Army (who had a high infestation incidence and a correspondingly high typhus morbidity rate at the early stages of the outbreak) as well as refugees and British Troops. Yugoslav prisoners were hospitalized under our direction in Italy. Many of these arrived with typhus. All were dusted with AL 63 on arrival, many having been previously dealt with in Yugoslavia before departure. This focus of infection produced no secondary cases in Italy.

The dust gun was such an admirable weapon that we commenced local manufacture, at first by Italian tinsmiths, and later in army workshops. Field hygiene sections also experimented with and turned out quantities of hand and power sprayers. All British troops were dusted with AL 63 weekly. A high standard of cleanliness was insisted on, and the usual regulations about visiting civilian establishments and contact with civilians generally were put into operation. Civilian public places were closed. A local typhus committee and an Allied Typhus Control Board were formed and supervised and directed preventive measures. Unfortunately, the shelter population could not be cleared owing to frequent enemy air raids, and the fact that there was no alternative housing accommodation during the day. This was, however, not entirely disadvantageous, for this section of the population was always available for treatment by the dusting teams who visited caves and shelters periodically.

After many difficulties the infectious disease hospital—badly bombed—was put into operation for housing the patients. A section of this was staffed by Lieut.-Colonel Stuart Harris, R.A.M.C., and his team assisted by 12 British Army Nurses, and members of the Friends Ambulance Unit. The work of these people, under conditions of extreme difficulty and a high degree of personal danger, was excellent. The U.S. Typhus Commission was assisted in the case searching, contact delousing and inoculation schemes by a number of R.A.M.C. Officers. British and U.S. Ambulances were used to augment the limited and indifferent Italian transport, but transport arrangements for the Typhus Commission personnel were inadequate throughout. From January 1 all mass and contact civilian dusting was done with D.D.T. under the organization of General Fox, U.S.A.M.C. (Up to a maximum of 70,000 daily, exclusive of the dusting with AL 63 of civilian employees and refugees.) The populace needed no compulsion to avail themselves of the service; they soon learned that almost immediate freedom from irritation resulted, and they gladly welcomed the change.

Subsequent progress of the epidemic.—Up to about January 9 cases rose rapidly to 65 daily, but afterwards there was a dramatic fall from 340 per week to half this number. At this time, Naples was placed out of bounds to all the Allied Forces except those on necessary duty. The curve remained steady for the ensuing three weeks, after which it again fell sharply to 40 early in February, and thereafter the epidemic gradually declined. 1,600 cases occurred in all. Cases outside the city increased at this time and continued for many weeks, owing to the imperfect control of civilian movement in and out of the city. There can be no doubt, taking into account the twelve-day incubation period, and the fact that few cases were notified before the fourth or fifth day, that the initial control of the epidemic was brought about as a result of intensive case searching and the ringing of contacts with barriers of insecticide. At this time D.D.T. was used only to a very limited extent. The usual anti-typhus measures employed must also have played an important part. The epidemic, checked by this initial onslaught, was given its final knock-out blow by the large-scale use of D.D.T.

During the whole epidemic only one British case occurred—a deserter, who was heavily infested when apprehended. No case was reported among the 20,000 to 30,000 civilian employees, and few in the Italian Army after December. AL 63 alone was used for dusting these groups.

The fight against the epidemic has been called the second battle of Naples, and undoubtedly, had it not been won, the Allied cause may well have been seriously endangered. Tribute must be paid to all who took part in the battle—the members of the U.S. Typhus Commission, the Rockefeller Foundation workers, A.M.G. and British and American Medical Services personnel, all of whom worked untiringly in full co-operation and harmony.

The lessons learned.—Naples taught us that an army can live and work in an overcrowded, war-damaged, typhus-ridden city, provided adequate precautions are taken. (Up to the middle of January, a relatively small proportion of British troops was protected by inoculation.) It showed us the benefits of mechanical methods of using insecticides on fully clothed subjects, and enabled the cumbersome steam and hot air disinfestors which took up so much transport, to be dispensed with. It also showed beyond question that D.D.T. was a new weapon of tremendous possibilities.

Technique of dusting.—This knowledge was used with advantage in preventing and treating infestation among the troops during the later stages of the campaign in Italy and in N.W. Europe and in dealing with the thousands of Axis prisoners and Allied ex-prisoners who passed through our hands at the cessation of hostilities. There was, however, need for education, and adherents of the old regime were sometimes hard to convince that dusting alone (at three intervals of a week) was sufficient. This was largely due to the fact that since the ova are not affected by dusting, a few lice were often discovered on members of units who had been treated a week previously. D.D.T. does not kill quickly, but its persistent action is a safeguard against the reinfestation which is always liable to occur after steam or hot air treatment of the clothing, although this method kills eggs and adults alike. Mechanical dusting enables large numbers of subjects to be treated quickly. The powder is applied to the head, forced up the arms, down the front and back of the neck and the pubic and gluteal regions. Except in cases of very heavy infestation it should not be necessary to introduce powder between different layers of clothing or to dust blankets and bedding.

MALARIA CONTROL.

The possibilities of D.D.T. as an anti-malaria measure were soon realized, and early in 1943 experiments were commenced in its use on the ground and in the air. An enormous amount of work was done by medical officers of the Allied Control Commission under the direction of Col. Paul Russell, the Rockefeller Team, and British and American malariologists. In addition, Major Cranford Benson, who was in charge of an Entomological Research Unit and who had carried out valuable pioneer work on impregnated shirts, continued his researches on the use of D.D.T. in the field. The information thus gained enabled a technique to be evolved which was put into operation during the malaria season with considerable success. It is believed, also, that the pioneer work was made use of in other theatres of war. The malaria danger in Italy was very great. Deliberate enemy sabotage had resulted in vast areas, like the Pontine Marshes, becoming once again dangerous breeding grounds, and the menace of a flooded Po Valley loomed ahead. The war had also brought about a cessation of civilian anti-malaria schemes, and the Italian Army from Sardinia provided a new and dangerous reservoir of infection. Fortunately, our fears of a large-scale malaria epidemic were not realized: the British Army morbidity rate was, in fact, lower than during the previous year. That the risk was there was evidenced by the civilian incidence in the Littoria province where at least 30,000 cases occurred during the summer of 1944 out of a population of 240,000. The cases occurred in that part of the province flooded as a result of destruction of pumping stations and canals, where the mosquito population was enormous. In similar areas, occupied by troops owing to operational necessity, where D.D.T. spraying was used, comparatively few cases occurred. As the 8th Army advanced, malaria control teams sprayed all houses, cowsheds, &c., with anti-mosquito spray using power sprayers. This gave a quick knock-out effect on mosquitoes. They were followed by teams who used 3 to 5% D.D.T. solution in kerosene; knapsack sprayers were used. There is hardly a house or animal-shed in Central and Northern Italy which does not give evidence of this on its walls, where the familiar white letters "D.D.T."—followed by the date and number of the malaria control unit carrying out the work—record the work done. The first essential of D.D.T. spraying is to use a coarse spray, and the happy medium between too fine a spray and a wasteful wet spray must be aimed at. It is necessary, therefore, that whatever spraying apparatus is used, the jet be of a suitable size—approx. 1/32 in. The jet of the apparatus should be held from 1½ to 2 feet from the wall surface. Although the lethal action of D.D.T. persists for about three months, spraying as an anti-fly or anti-mosquito measure should be repeated monthly: a quart of a 5% solution will treat 1,000 square feet.

Toxic effects.—No ill-effects were noticed during the treating of more than a million civilians in Naples with 10% D.D.T. in talc, neither were the operators who were always white with dust adversely affected. Masks, gloves and gas capes were used by the Army operators of D.D.T./Kerosene solutions, because exact information as to the toxicity of these solutions was not known. Two workers were affected, but the symptoms were suggestive of heat-stroke. It is considered that reasonable precautions should always be taken, not only because of a possible D.D.T. absorption, but also against a kerosene risk. Mechanically unsound apparatus in which there is much leaking should not be used: it is wasteful and adds to the risks of the operator.

Paints and distempers.—The use of oil-bound water paints and distempers in which 5% D.D.T. is incorporated were experimented with. This method of treatment of cookhouses, messrooms and latrines has great possibilities.

CONCLUSIONS

D.D.T. is undoubtedly the most remarkable insecticide yet produced and provides the worker in preventive medicine with a new weapon of tremendous power. It played a big part in protecting our Armies overseas. The knowledge thus gained should be made use of fully in civilian life. But the question must be asked: is it yet safe for general use? Details have already been made known of its lethal effect on benign insects such as bees and ladybirds and even minnows and trout, snakes and frogs are said to have been killed following spraying from the air. Preparations labelled "D.D.T." are now on sale to the public in many chemists' shops, grocers and ironmongers and general stores. The cartons I have seen give no information as to the strength of D.D.T. or the nature of the vehicle in which it is contained, neither are there any instructions as to how the preparation should be used. The public are liable to use it indiscriminately and wrongly, and it is felt that its sale should be controlled, and that full details of the composition of each product should be clearly marked on the container. The suggestion is made that these matters should be dealt with by legislation as quickly as possible.

Major K. R. Hill described a fatal case of D.D.T. poisoning in a child (*see Brit. med. J.*, 1945 (ii), 845).

Dr. R. A. M. Case referred to experiments carried out at the Royal Naval Physiological Laboratory (*see Brit. med. J.*, 1945 (ii), 842).

Lieut.-Colonel F. F. Hellier (late Adviser in Dermatology, B.L.A.): The B.L.A. was the first force to go overseas with D.D.T.-impregnated shirts. They went to France in June and by September cases of dermatitis undoubtedly associated with shirts, began to appear. Recently in Germany as many as 300 to 400 a month have been seen. The dermatitis affected those areas where the shirt was pressed against the skin and in most cases there was an associated purpura on the areas involved. Numerous tests with D.D.T. both as a powder and in various bases were almost consistently negative and I am sure the irritant agent is not D.D.T. as such. We wondered whether some alteration might occur in D.D.T. during washing, &c., but all our investigations have failed to convict D.D.T. It is, however, a striking fact that this rash has been limited almost entirely to B.L.A., which was the one army using impregnated shirts.

The men went over to France in a remarkably clean state, the incidence for both lousiness and scabies being only 1 per 1,000 per month. This state of affairs continued as long as they remained in Normandy, but on moving into Belgium and Holland where they came into closer contact with the civilians, the incidence of scabies, and pediculosis pubis rose by eight or ten times, whilst that of pediculosis corporis remained steady. This could only be attributed to the D.D.T., though why it did not affect pediculosis pubis is difficult to say. As I have shown elsewhere (*see Brit. med. J.*, 1945 (ii), 255) D.D.T. does not affect scabies.

Dr. C. J. Hackett asked Colonel Chalke what dose of mepacrine was being taken in Italy at the time and place in which he said D.D.T. had been so effective in combating malaria. He knew areas in Burma during the war where considerable D.D.T. usage was associated with low malarial incidence and vice versa. At the same time, however, good suppressive mepacrine discipline was practised in the areas of low malarial incidence—and vice versa.

Dr. C. C. Chesterman asked whether there was any pathological evidence of degeneration of the basal ganglia in human beings poisoned by D.D.T. The symptoms suggested it and it would be interesting if a poison so toxic to insects were specific for the more primitive neurons of the brain.

Dr. Chalke (in reply) said that a daily mepacrine tablet was ordered for all fighting troops and certain base troops, but discipline was variable and generally only fairly good. He felt that D.D.T. control had proved effective. Units staging or camping in uncontrolled malarious areas always suffered severely from malaria.

Neurological Experiences in the Middle East and India

By DOUGLAS McALPINE, M.D., F.R.C.P.

NEUROLOGY in the Services in the Middle East and India was mainly concerned with infections of the central and peripheral nervous systems. There were striking differences in the susceptibility of British and Dominion troops as compared with Indian troops. For example, acute poliomyelitis was relatively common in the former, but distinctly rare in Indian troops, whilst in India, acute toxic polyneuritis was rare amongst British troops, but commoner than poliomyelitis in Indian personnel. Diphtheria was so rare in Indian troops that I personally have not met with a case of polyneuritis due to that cause in an Indian. And lastly, meningococcal meningitis was practically confined to Indian and African troops.

MENINGITIS

Meningococcal meningitis.—In India, two factors were responsible for outbreaks of meningococcal meningitis during the winter months. First, the inevitable overcrowding which resulted from the rapid expansion of the Indian Army, and secondly, malnutrition, particularly in recruits to labour battalions. During the first ten months of 1943 approximately seventeen hundred cases were notified. The mortality rate exceeded 15%. An attempt was made between 1943 and 1945 to reduce both the incidence of the disease and the mortality rate, by propaganda amongst O.C.s of Indian units and their medical officers to ensure that there was a minimal delay in cases reaching hospital, and by raising the standard of medical and nursing care in hospitals. Late in 1944, in addition to these measures, a trial of sulphamezathine was made. Early in that year this drug was introduced into India for use by neurosurgical units. It was found that large doses, namely 3 grammes four-hourly, given intravenously, were necessary in order to maintain a C.S.F. concentration of 10 mg.% (Johnson and Dick, 1945). With these doses meningitis in head wounds was effectively controlled. Similar doses were recommended for use in severe cases of meningococcal meningitis. In addition, the feeding of comatose patients by means of an intragastric Ryle's tube, and the nursing of patients in a propped-up position, as practised by Lieut.-Colonel G. Ransome, I.M.S. (1944), in the treatment of cerebral malaria were advocated. A trial of these methods was made in a number of hospitals throughout India. I am indebted to Brigadier B. Schlesinger, Consulting Physician, for the following figures relating to Central Command.

Year	Total	Deaths	Mortality Rate
1943	863	113	13%
1944	418	42	10%
1945 (1st qtr.)	106	7	6.6%

Two of the deaths in 1945 were due to the fulminating form of the disease; sulphamezathine was not given in either of these cases.

Acute benign lymphocytic meningitis.—From 1941 onwards, a lymphocytic type of meningitis was seen in the Middle East in increasing numbers, and at first the classification of these cases was difficult. Many of them closely resembled sandfly fever, but after some months it became clear that in this condition a true meningitis is rare. It was noted that the majority of cases occurred during the spring and summer months. The onset was characterized by malaise, fever, headache, vomiting and a considerable degree of prostration. Neck stiffness was present in varying degrees; Kernig's sign was usually negative. The deep reflexes were normal, depressed or rarely absent. Drowsiness was a feature in some cases, but signs of encephalitis were absent. The average duration of the fever was five days. Recovery was rapid, and no relapses or organic sequelæ occurred. The cell increase in the C.S.F. varied from 20 to several hundred cells, mainly lymphocytes. The fluid returned to normal within three weeks. Neutralization tests in some of these cases proved that the majority were not due to the virus of acute chorio-meningitis. No proof of case-to-case infection was found, nor were there any features to suggest droplet spread; on the other hand no vector could be traced. In 1941 abortive cases of poliomyelitis were reported by Major J. Caughey, N.Z.A.M.C., thus making the sorting out of these cases of lymphocytic meningitis more difficult.

In the latter part of 1941 cases began to crop up which resembled acute benign lymphocytic meningitis, but differed from them in that one or more relapses of headache and

fever occurred after seven to ten days. When, in addition to this feature, a few of these cases developed either signs of encephalitis or facial palsy, it became clear we were dealing with tick-borne relapsing fever.

NEUROLOGICAL COMPLICATION OF TICK-BORNE RELAPSING FEVER

In the Middle East infection occurred amongst British, Dominion and Indian troops particularly in the Western desert, although cases also occurred in Palestine, Syria and Cyprus (Cooper, 1942; Scott, 1944). The strains of spirochæte included *Sp. recurrentis* and *persica*, both of which are highly neurotropic in animals. In order to estimate the frequency with which the nervous system is involved in man, it would be necessary to examine the C.S.F. at intervals in every case of relapsing fever; this was impossible under wartime conditions, but I had the impression that the nervous system was frequently invaded. I have notes of 84 cases in which neurological signs were present:

(a) *Meningitis*.—This occurred in 80 of the 84 cases (95%). It may be noted as early as the second or as late as the eighth relapse of fever. Severe headache is the characteristic symptom. Signs of meningitis are not always present. As a rule with each recurring bout of fever the meningeal signs become more acute. The C.S.F. shows a pleocytosis which may vary from 20 to over 2,000 cells per c.mm. Lymphocytes predominate or may constitute the total cell count. The protein content is increased, sometimes exceeding 150 mg. in the more chronic cases. The W.R. may become positive and the fluid may give a paretic colloidal gold curve. These two findings are sometimes dissociated, the paretic curve being more common than a positive W.R. As a rule the fluid returns to normal within a few weeks of the cessation of fever; rarely the fluid may be abnormal for six months from the onset.

(b) *Meningo-encephalitis*.—24 of the 84 cases (28%) showed encephalitic signs, which appeared between the third and eighth week. Drowsiness is a marked feature; when roused, the patient shows a lack of facial expression and is mentally dull. Diplopia is relatively common. Unilateral or bilateral pyramidal signs may be present, while cerebellar signs consisting of nystagmus, dysarthria and ataxia or tremor of the limbs are not infrequent.

(c) *Facial palsy*.—18 of the 84 cases (21%) showed a facial palsy of peripheral type. It appears between the third and tenth week of the disease and is usually accompanied by fever. In 4 cases the condition was bilateral and in each of these cases a few days to a week elapsed before the face on the opposite side was affected. In only 4 of the 18 cases were definite signs of encephalitis present. Not infrequently there is relative sparing of the frontalis, but otherwise the condition resembles the ordinary form of Bell's palsy. Pain was not a feature, and in those cases in which it was tested, taste was usually reported as normal. Hearing was not affected. In 14 of the 16 cases in which the C.S.F. was examined, a pleocytosis was present.

(d) *Eye complications*.—Papilloedema occurred in 11 of the 84 cases (13%), usually in the later stages of the disease. It was associated with a rise of C.S.F. pressure. With repeated lumbar puncture the condition slowly subsided, but in 3 cases it persisted for some weeks. Loss of vision may be due to a papillitis, to an iridocyclitis or to a uveitis. These complications are comparatively rare.

The following case illustrates some of the complications already mentioned:

Lieutenant R. M., aged 29, left Tobruk on June 25, 1942. About the middle of July he developed fever and this recurred at weekly intervals. On August 24 he was admitted to hospital with severe headache and vomiting of four days' duration. Temperature 100°. Except for neck stiffness there were no physical signs. The C.S.F. contained 485 cells per c.mm., mainly lymphocytes and 100 mg. protein. Blood films were negative for spirochætes. The headache persisted during the next week. At the beginning of September he felt much better, but the C.S.F. showed a strongly positive W.R., with a paretic type of Lange curve. Blood W.R. was negative. He received arsenical treatment, but a degree of headache persisted. The C.S.F. pressure varied between 130 and 170 mm. during the first two weeks in hospital, but by September 14 had risen to 190 and early papilloedema was noted. On September 17 severe headache with meningeal signs recurred. The C.S.F. findings were unaltered. By the end of September he was free from headache and the fundi were normal. The C.S.F. pressure was 140, lymphocytes 33 per c.mm., protein 65 mg. W.R. doubtful. Lange curve 5543331000. He was discharged to a convalescent depot on October 21. On November 26 he reported to hospital feeling quite fit. The C.S.F. was normal in every respect. In this case the spirochæte was never isolated despite many examinations.

On the whole the prognosis as regards neurological sequelæ is favourable. In a small percentage of cases signs of a chronic meningo-encephalitis persist for some weeks after fever has ceased. Headache, impairment of memory, efficiency and initiative may be noted. The C.S.F. is usually abnormal. Since the more chronic cases were evacuated it was impossible to follow them up.

Treatment.—Arsenical preparations were disappointing, both in the early and late stages. However, we had the impression that cases untreated initially were more prone

to develop neurological signs. In future, the effective control of this disease will be possible by the use of penicillin.

ACUTE POLIOMYELITIS

This disease was of importance in the Middle East and India for two reasons. First, it was commoner than in the U.K., and, secondly, there was a high mortality, ranging from 18% to over 30%. In addition, there were facts of considerable epidemiological interest (Seddon *et al.*, 1945; McAlpine, 1945).

Prodromal symptoms lasting two to ten days were the rule. In many cases the symptoms cleared up after two or three days, only to return a few days later and be followed by signs of invasion of the nervous system. This constitutes the so-called dromedary type of prodromata as described by Draper (1917).

These prodromal symptoms could be roughly divided into three groups:

(1) The influenzal group characterized by headache, shivering, malaise, anorexia, backache and pains in the limbs.

(2) The catarrhal group in which some of the above-mentioned symptoms were associated with sore throat, coryza or a cough.

(3) The gastro-intestinal group in which vomiting and diarrhoea were prominent. It is probable that in many individuals these symptoms were not followed by paralysis, but the detection of these abortive cases in tropical countries, except during an epidemic, is a matter of great difficulty. These cases are important since we now know that the virus is usually present in the stools of such cases, and consequently they may play a part in the further dissemination of the disease. It seems clear that in acute poliomyelitis there is a preliminary phase of systemic infection and that the invasion of the nervous system by the virus may depend on local factors in the throat or intestine which favour its passage to nervous tissue.

With regard to the distribution of the paralysis, in the majority of cases the lower dorsal and lumbosacral cord bore the brunt of the disease. The paralysis was often roughly symmetrical. As a rule the muscle groups acting on the hip and knee joints were more affected than the distal muscles. The lower abdominal and erector spinae muscles often shared in the paralysis. In the Middle East and India approximately 50% of all cases had retention of urine; this was usually temporary, but in a small percentage of cases a suprapubic cystostomy was necessary.

Turning to the mild cases, localized and symmetrical paralyses were occasionally met with. For example, I have seen paralysis limited to the masseters in one case, and to the sternomastoids in another.

Fatal cases fell into two groups: (1) The ascending type, and (2) the cervico-bulbar or bulbar type. The ascending type was common in the Middle East and India. The rapid and relentless upward spread of the disease from the lumbar cord in a previously healthy individual was a picture with which we became all too familiar. The majority of bulbar cases were fatal, although a few survived. Death might take place suddenly as in the following case:

Major J. C. B., aged 32, travelled from Delhi to Calcutta on November 27, 1944. On November 30 he complained of headache, vomiting and dizziness. He was admitted to hospital on December 2. His temperature was 100.4°. He was drowsy and complained of headache, but meningeal or other abnormal signs in the central nervous system were absent. The cerebrospinal fluid showed a normal cell and protein content. Fever continued, and on December 5 he complained for the first time of slight difficulty in swallowing, but his speech and breathing were normal. He now showed slight neck rigidity. His condition remained the same until the following afternoon when he asked for a bed-pan. A few minutes later he became incoherent and died. At post-mortem there were changes typical of polio-encephalitis.

We encountered quite a few cases in which the C.S.F. was normal either during the meningitic or paralytic phase of the disease. I roughly estimated such cases to constitute 5% of the total.

Treatment.—The use of iron lungs in tropical climates necessitates either the nursing of the patient in an air-conditioned room, or, less satisfactorily, the reduction of temperature inside the lung by means of ice placed on a tray. A team of medical officers, sisters and nursing orderlies who have had previous training in the use of this instrument is essential. An iron lung is useless in cases of bulbar palsy. Survival may depend on keeping the airways clear, preferably by a rubber tube attached to a suction apparatus; this is not possible with a patient in an iron lung.

Persistent pain in the paralysed limb was frequently met with. Failure to relieve the pain by heat and analgesics, and to maintain a full range of passive movements, resulted in stiff joints.

In India we confirmed the value of a swimming pool during the convalescent stages. Not only are exercises carried out to better advantage under water, but this treatment shares first place with occupational therapy in maintaining morale.

fever occurred after seven to ten days. When, in addition to this feature, a few of these cases developed either signs of encephalitis or facial palsy, it became clear we were dealing with tick-borne relapsing fever.

NEUROLOGICAL COMPLICATION OF TICK-BORNE RELAPSING FEVER

In the Middle East infection occurred amongst British, Dominion and Indian troops particularly in the Western desert, although cases also occurred in Palestine, Syria and Cyprus (Cooper, 1942; Scott, 1944). The strains of spirochaete included *Sp. recurrentis* and *persica*, both of which are highly neurotropic in animals. In order to estimate the frequency with which the nervous system is involved in man, it would be necessary to examine the C.S.F. at intervals in every case of relapsing fever; this was impossible under wartime conditions, but I had the impression that the nervous system was frequently invaded. I have notes of 84 cases in which neurological signs were present:

(a) *Meningitis*.—This occurred in 80 of the 84 cases (95%). It may be noted as early as the second or as late as the eighth relapse of fever. Severe headache is the characteristic symptom. Signs of meningitis are not always present. As a rule with each recurring bout of fever the meningeal signs become more acute. The C.S.F. shows a pleocytosis which may vary from 20 to over 2,000 cells per c.mm. Lymphocytes predominate or may constitute the total cell count. The protein content is increased, sometimes exceeding 150 mg. in the more chronic cases. The W.R. may become positive and the fluid may give a paretic colloidal gold curve. These two findings are sometimes dissociated, the paretic curve being more common than a positive W.R. As a rule the fluid returns to normal within a few weeks of the cessation of fever; rarely the fluid may be abnormal for six months from the onset.

(b) *Meningo-encephalitis*.—24 of the 84 cases (28%) showed encephalitic signs, which appeared between the third and eighth week. Drowsiness is a marked feature; when roused, the patient shows a lack of facial expression and is mentally dull. Diplopia is relatively common. Unilateral or bilateral pyramidal signs may be present, while cerebellar signs consisting of nystagmus, dysarthria and ataxia or tremor of the limbs are not infrequent.

(c) *Facial palsy*.—18 of the 84 cases (21%) showed a facial palsy of peripheral type. It appears between the third and tenth week of the disease and is usually accompanied by fever. In 4 cases the condition was bilateral and in each of these cases a few days to a week elapsed before the face on the opposite side was affected. In only 4 of the 18 cases were definite signs of encephalitis present. Not infrequently there is relative sparing of the frontalis, but otherwise the condition resembles the ordinary form of Bell's palsy. Pain was not a feature, and in those cases in which it was tested, taste was usually reported as normal. Hearing was not affected. In 14 of the 16 cases in which the C.S.F. was examined, a pleocytosis was present.

(d) *Eye complications*.—Papilloedema occurred in 11 of the 84 cases (13%), usually in the later stages of the disease. It was associated with a rise of C.S.F. pressure. With repeated lumbar puncture the condition slowly subsided, but in 3 cases it persisted for some weeks. Loss of vision may be due to a papillitis, to an iridocyclitis or to a uveitis. These complications are comparatively rare.

The following case illustrates some of the complications already mentioned:

Lieutenant R. M., aged 29, left Tobruk on June 25, 1942. About the middle of July he developed fever and this recurred at weekly intervals. On August 24 he was admitted to hospital with severe headache and vomiting of four days' duration. Temperature 100°. Except for neck stiffness there were no physical signs. The C.S.F. contained 485 cells per c.mm., mainly lymphocytes and 100 mg. protein. Blood films were negative for spirochaetes. The headache persisted during the next week. At the beginning of September he felt much better, but the C.S.F. showed a strongly positive W.R., with a paretic type of Lange curve. Blood W.R. was negative. He received arsenical treatment, but a degree of headache persisted. The C.S.F. pressure varied between 130 and 170 mm. during the first two weeks in hospital, but by September 14 had risen to 190 and early papilloedema was noted. On September 17 severe headache with meningeal signs recurred. The C.S.F. findings were unaltered. By the end of September he was free from headache and the fundi were normal. The C.S.F. pressure was 140, lymphocytes 33 per c.mm., protein 65 mg. W.R. doubtful. Lange curve 5543331000. He was discharged to a convalescent depot on October 21. On November 26 he reported to hospital feeling quite fit. The C.S.F. was normal in every respect. In this case the spirochaete was never isolated despite many examinations.

On the whole the prognosis as regards neurological sequelae is favourable. In a small percentage of cases signs of a chronic meningo-encephalitis persist for some weeks after fever has ceased. Headache, impairment of memory, efficiency and initiative may be noted. The C.S.F. is usually abnormal. Since the more chronic cases were evacuated it was impossible to follow them up.

Treatment.—Arsenical preparations were disappointing, both in the early and late stages. However, we had the impression that cases untreated initially were more prone

dysentery was observed in German prisoners of war in the Middle East by Spillane and Scott (1945). Similar cases have recently been seen in India in British and Indian troops returned from captivity.

HEAT STROKE

In India heat stroke was one of the principal medical causes of death amongst British other ranks. Improved methods of treatment have led to a lowering of the mortality rate, but as might be expected, some of the men who survived showed permanent sequelæ. The effects of heat stroke on the brain are at first generalized. On recovery from coma a variety of signs may be present, including severe mental confusion with incontinence, aphasia, pyramidal and cerebellar signs. As recovery proceeds the patient becomes orientated, ceases to confabulate, shows progressive improvement in memory, and is no longer incontinent. In short, the mental picture is very similar to that seen after a severe head injury. In a small percentage of cases this favourable course is not followed, a gross memory defect, both for recent and past events, persists and is accompanied by lack of interest, childish behaviour and incontinence. These signs of dementia vary in their severity and in the extent to which they eventually clear up. Inability to talk may be due to aphasia or to a gross dysarthria; both of these defects may be found in the same patient. Signs of a unilateral or bilateral hemiplegia clear up as a rule, although incompletely in some cases.

The most interesting sequel to heat stroke is a cerebellar picture. In July 1942 I examined three men in the Middle East who had recovered from heat stroke; all three were dysarthric and showed ataxia in their limbs, and unsteadiness in walking. None showed nystagmus. In two of these cases the signs cleared up in the course of a few weeks, but in the remaining case they persisted in association with signs of a gross dementia. In India I saw several similar cases, of which the following is an example:

Sergt. P., aged 40, on June 17, 1944, travelled 100 miles in a lorry west of Calcutta. He arrived at his destination in coma and was at once admitted to hospital where his rectal temperature was found to be 110°. Blood slides were negative for malarial parasites. He received energetic treatment for hyperpyrexia. On the evening of June 19 he recovered consciousness. He was moderately confused and incontinent. His speech was grossly dysarthric. He continued to improve slowly. On July 24 he appeared euphoric and showed involuntary laughter. He was well orientated and his memory was only slightly impaired for recent events. There was a rotatory nystagmus, especially to the right. Gross ataxia was present in both upper and lower limbs and he was unable to stand unsupported. The jaw-jerk was increased and there were signs of mild double hemiplegia. The picture he presented was very similar to that seen in advanced disseminated sclerosis. Two months later his condition was virtually unchanged.

Similar cases have been reported by Weisenberg (1912), R. M. Stewart (1918), and recently by Freeman and Dimoff (1944). Stewart postulated a cortical cerebellar lesion in his case and Freeman and Dimoff reported a case fatal on the third day in which changes in the cerebellum were maximal in the region of the Purkinje cells. Although in the case I have cited nystagmus was present, as a rule it is absent. Confirmation of a cortical cerebellar atrophy in these cases has been found by Major L. Krainer, R.A.M.C., a neuropathologist working in India.

An Unusual Form of Epidemic Food-Poisoning with Neurological Symptoms

By DENIS BRINTON, F.R.C.P.

For thirteen months from October 1942 the population of Aden had been intermittently affected by epidemics of this food-poisoning. Perhaps 450 persons in all had suffered; and from the first (although the authorities did not learn this till much later) the natives had correctly blamed the Abyssinian wheat which had been shipped to Aden from the earliest harvest after the fall of the Italian East African territories, to save the better-quality Dominion-supplies, then very short for a number of reasons. According to the sufferers, this Abyssinian wheat was not only of poor quality, but contained a poisonous weed-seed, called in the local arabic *niscara*, literally to be translated as "tipsy", which you will see is a first-rate description of the effects it produces in man.

POLYNEURITIS

(a) *Diphtheritic*.—Several hundred cases of polyneuritis occurred in British and Dominion troops serving in the Middle East between 1940 and 1943. Nearly all of these cases were due to diphtheria. In India, diphtheria was uncommon during the war until the second half of 1944 when about 200 men of a special force employed in Burma were evacuated with polyneuritis which proved to be diphtheritic.

Both in the Middle East and India, approximately one-third of the cases were considered to be due to cutaneous infection. In cases with a cutaneous lesion and a history of a sore throat, it was not always easy to decide which was the focus of infection. If there was a history of paralytic throat symptoms then the case was considered faucial, but if such signs had never been present then an extrafaucial focus was presumed. Many cases of faucial infection were atypical either because of an associated streptococcal infection or because the throat signs were slight; consequently at times there were delays in administering serum, and this delay increased the risk of paralysis. Cutaneous infections were remarkable for their variety. The commonest lesion in the Middle East was the desert sore and in Assam and Burma its counterpart the jungle sore. Examples of polyneuritis were seen following a diphtheritic infection of a whitlow, scabies, an abscess, an infected in-growing toenail, and an infected hemorrhoid.

Diphtheritic infection of wounds was rare both in the Middle East and India. I have nothing to add to the excellent description of these cases given by Dr. Walshe in 1919 based on his experience in the M.E. during the first World War (1917, 1918). He divided the paralytic signs into local, specific and generalized. In a series of 30 cases of polyneuritis following skin infection he noted in 27% of these cases an onset of paralysis anatomically related to the infected focus. We have questioned many cases in this war as to whether the weakness began in the limb affected by the principal skin lesion, and have examined them from the point of view of an asymmetrical weakness corresponding to the infected limb, but the percentage of cases giving positive evidence of a local paralysis has been small. Localized numbness with or without sensory loss has been found somewhat more frequently. On the other hand, a certain number of typical cases of local palsy have been seen which support the general truth of Dr. Walshe's observations.

It is difficult to understand why paresis of accommodation, since it is a specific sign, should apparently be less common in extrafaucial as compared with faucial infection. An explanation may lie in the fact that following cutaneous infection there may be no local paralysis, and that a slight degree of paresis of accommodation, particularly in men engaged in active operations in the Field, may pass unnoticed or be forgotten by the time polyneuritic symptoms develop. Major A. D. Leigh, R.A.M.C., in an analysis of 100 cases of diphtheritic polyneuritis found that there was little difference in the incidence of paresis of accommodation in faucial and extrafaucial cases. With regard to treatment, in the early years of the war there was a tendency to immobilize severe cases in bed for weeks on end. Lieut.-Colonel Garland, R.A.M.C., who was in charge of a Neurological Centre in S. India, found that rapid improvement is possible, even in cases with gross postural loss, by means of exercises at first carried out in bed and later in a class under the supervision of a masseuse and P.T. Instructor. Since cases did not, as a rule, reach this centre for at least six weeks after infection, serious myocardial complications were not seen, and minor degrees of effort syndrome soon cleared up under this régime. No uncomplicated case of diphtheritic paralysis was evacuated to U.K. by this centre during 1944.

(b) *Nutritional*.—Polyneuritis complicating typhoid was occasionally seen. For example, in 1942 in one hospital in the Middle East I saw four such cases in which there was a history of prolonged fever and mental confusion which had led to difficulties in feeding. In two of these four cases, deafness preceded the onset of polyneuritic symptoms. In scrub typhus tenderness of the calves and feet is relatively common in severe cases, whilst a fully developed polyneuritic picture is not a rarity. The explanation is the same as in typhoid, namely inadequate feeding. In scrub typhus nerve deafness is common, but occurs independently of a polyneuritis. Several examples of Wernicke's encephalopathy were seen. The following is the history of one such case which I saw in the Middle East:

Lieutenant M., aged 29, was admitted to hospital on October 24, 1941, with infective hepatitis of one month's duration. Complete anorexia and frequent vomiting persisted after admission. The calorie intake was less than 500. On November 16 he complained of numbness round his knees. On November 27 double vision with a partial external ophthalmoplegia and nystagmus were noted. On December 2 he appeared emaciated and ill. There was no mental confusion. The ocular findings were confirmed. There was numbness with slight sensory loss on the feet. A diagnosis of Wernicke's encephalopathy was made. Treatment by daily injections of aneurin and additions to the diet resulted within a fortnight in rapid improvement in his general condition, cessation of vomiting, a return of appetite and disappearance of the eye signs; however, polyneuritic signs became more evident and persisted for some weeks.

A syndrome of great interest resulting from the association of a defective diet with

might also have been obtained. But hundreds of tons, not a few bushels, were needed; and primitive methods were totally inadequate to clean such quantities, even if the Ethiopian small-holder had somehow developed such an improbable concern for the fate of his brothers in Aden.

Nutritional Disorders of the Nervous System in the Middle East

By J. D. SPILLANE, M.D.

Nutritional polyneuritis.—In the Middle East during 1942-43 Polish troops and refugees filled some of the camps and hospitals of Paiforce and Palestine on their evacuation from Russia. Most of them had escaped into or had been transported to Russia in the winter of 1939-40. For two years they endured considerable hardships there and after the German invasion many of them were transported across the Caucasus to Iran, Iraq and Palestine. I had the opportunity of seeing many hundreds of these unfortunate people. Dysentery, malaria and typhoid were very common among them. Many were tuberculous. Malnutrition was widespread. Especially in the officer class one observed considerable loss of flesh; glossitis, œdema of the ankles, chronic diarrhœa were very common. A few had scurvy. Many of them had symptoms and signs of polyneuritis. Two types of case were encountered.

In the first and largest group symptoms dated back some six or twelve months. Difficulty in walking was the earliest complaint. Sharp pains in the soles of the feet and in the calf muscles would arrest progress and force the patient to rest—as in claudication. Affected individuals found difficulty in keeping their feet warm, painful dyæsthesiæ distressed them, especially at night. Muscle tenderness, wasting, weakness of the extensors of the toes and feet, sensory loss and reflex disturbances subsequently made their appearance in many cases. In the second group the onset of paralysis was quite rapid and almost always occurred during or shortly after an acute infective illness such as malaria, dysentery or typhoid. And yet I can say that I never once saw, during three years, a case of polyneuritis in a British soldier during such infections. Post-diphtheritic and acute infective polyneuritis were readily excluded in these Polish patients. A few fatal cases had terminal signs of brain-stem involvement—diplopia, ophthalmoplegia, paresis of the tongue musculature—and at post-mortem there were typical vascular lesions of the Wernicke type. But these hæmorrhagic lesions in the brain-stem were sometimes found where no localizing signs had been demonstrated ante-mortem (in some cases after careful observation).

On one occasion brief examination of the nervous system of all patients in one hospital ward revealed that about 25% had reduced or absent knee and/or ankle jerks. The majority were suffering from the acute infections of the type mentioned. I came to the conclusion that the neurological disturbance was one of nutritional polyneuritis. Many of them were already on vitamin-B therapy and one was able to watch the progress of nearly all of them (60 cases) during the following six to nine months. Thiamine when given intramuscularly seemed to improve appetite, relieve the sharp pains in the legs and feet and possibly increased the sense of well-being of some of the patients. But it had no effect whatever on the period of incapacity. Over and over again initial improvement of a subjective kind was thought to herald definite objective cure. Occasionally one observed some shrinkage of the area of sensory loss, but restoration of muscular power and reflex activity were never hastened. Yet these are the very signs which denote morphological alteration in the peripheral nerves and if consistently reversed would indicate some specific healing properties in the vitamin.

Since then I have had similar experiences with native and European prisoners of war and internees, in the Middle East and in the United Kingdom, and observation of over 200 cases of polyneuritis in these malnourished individuals has provided ample data on which the general effects of thiamine therapy may be judged. I have no strictly controlled series of cases to substantiate my conclusions—but they were never necessary. Routine clinical observation of cases which received adequate treatment with thiamine, by all channels, or who were given courses of treatment lasting one or two weeks (20 to 100 mg. daily), showed quite clearly that they fared no better than cases who received no additional supplements of vitamin.

On this problem of the "antineuritic vitamin" it seems probable that there is a large body of unpublished experience which indicates the inertness of vitamin B₁ in the treatment of polyneuritis. If general experience in the last ten years had established the value of thiamine we should not now have to debate the problem. The acceptance of liver and insulin therapy was never so long delayed, and there is no reason to suppose that a cure for polyneuritis will not be recognized when it appears. I do not think my clinical experience is necessarily in disagreement with the demonstration by the bio-

The natives insisted that this miscara was a common weed in every wheat-field of the Aden-peninsula also; and that, though they had never heard of any case of poisoning from the local crop, the greatest care had always been exercised by the farmers to remove the weed and its seeds from the wheat, at all stages from harvest to milling. In samples of Abyssinian wheat, they showed me how to recognize miscara, and in the hilum of many of these grains pointed to a black discoloration which under a hand-lens presented a mouldy appearance. Several samples of newly wharfed Ethiopian grain were collected and counted, and found to contain miscara-seeds in quantities up to 10%.

Reconstructing the clinical aspects of this food-poisoning by questioning both those who had suffered and the doctors who had had charge of them when ill (for the Governor had rightly frozen all stocks of the poisoned wheat a few days before I arrived, and the epidemics had come to an abrupt end), I learnt that, from one-quarter of an hour to two hours after taking food made of this grain, a man would become dizzy, and be smitten with headache, marked generalized tremors, lassitude, slurred speech, and a staggering gait. Sometimes, there had been vomiting and diarrhoea, and less commonly nausea and abdominal pain. Subsequent events seemed to vary directly with the amount of poison taken. If the subject had fed well, he paid for it by quickly subsiding into stupor or even a coma from which it might be impossible to rouse him for so long as ten hours; but, if he had taken only a little, his earliest symptoms would not noticeably increase and he might be fully recovered in three or four hours. There were no deaths, and within seventy-two hours even the most severely affected were well enough to resume their usual occupations.

Specimens of miscara sent home for botanical and chemical analysis revealed it to be a weed called the flax-darnel (*Lolium linicolum* or *temulentum*); and suggested that the poisonous element was in the mould to be seen on nearly every weed-seed, and was probably a pyridine-base of incompletely established chemical composition, known as temuline.

There were, however, certain paradoxes, necessarily slurred over in this bald statement of fact. First, it had to be established why Abyssinian wheat had proved poisonous to the inhabitants of Aden, though it had long been used in East Africa by the Italians, and more recently by us, without ill-effects. Secondly, I wished to find out how the natives of Aden came to have such an exact knowledge of miscara, although none could recall a case of poisoning from the local wheat, or indeed until the imports from Ethiopia began in 1942.

As to the first problem, a visit to a standard Italian mill in Eritrea provided the answer. Here, Ethiopian wheat, not less filthy, not less charged with miscara-seeds, was put through a complicated system of specially designed mechanical sieves before the wheat was milled. The resulting flour, long fed to the people of Eritrea and Abyssinia, was of course harmless; but Aden, without any sieving devices for cleaning the contaminated grain, had milled miscara with wheat and become poisoned.

As to the second paradox, the only explanation was the traditional usages of the small farmers of the Aden protectorates. No case of miscara-poisoning from locally grown wheat could be recalled, merely because from time immemorial scrupulous attention had been paid to the removal of the weed and its seeds from the harvested wheat. The miscara-plant, they said, is easily identified from the time when the crop has grown to a height of about one foot; it is a darker green than the wheat, and splits a short distance above the ground into five or six heads. Before the crop is cut, which in these extremely primitive communities is done by grasping a stool of stalks and severing them near their base with a curved knife, as much miscara as possible is weeded out; but some is unavoidably cut with the wheat, and is spread out with it in a clean place to dry in the sun. When these products of the harvest are dry, most of the grain is removed by a heavy stone drawn by oxen. Afterwards, what remains attached is hand-picked from the stalks, and all the free grain is then winnowed and housed. As wheat is required for food, the women take the grain from store and once more spread it in the sun. After it is warm, it is tossed up again and again in a straw-basket, so that light impurities such as husks are blown away. The same process flicks most of the miscara-seeds to the edge of the basket, whence they are readily removed. The residue is finally hand-picked, grain by grain, until all dirt, miscara-seeds, and other foreign bodies are separated. With these precautions, clearly applicable only to small holdings, local wheat can always be eaten with safety.

So, in essence, these epidemics of food-poisoning arose from the wartime marriage of primitive methods of agriculture to modern methods of distribution. If the Abyssinian harvest had been put through modern threshing machines, with their ordered winnowing arrangements, no seeds smaller than mature wheat-grains would have been exported to Aden, and the seeds of the flax-darnel would have been excluded. If the project could have been on a small enough scale to allow the hand-picking just described, clean wheat

none other than acute Wernicke's encephalopathy. Some authorities consider that breast-milk intoxication is a special variety of infantile beriberi.

In the German cases pellagra and ariboflavinosis were *not* present when they were under observation and only a few gave a history of such affections. Treatment was largely unsuccessful in clearing up the neurological signs. There was subjective improvement but the number which showed objective relief was small. Yeast, liver, nicotinic acid, riboflavine and thiamine were freely used for long periods.

ÆTIOLOGY

Vitamin A.—It has not been shown that vitamin A is concerned with the functioning of the nervous system. The nervous lesions in growing animals deprived of the vitamin are mechanical in origin. Blindness, deafness and ataxia have been satisfactorily explained on the basis of disproportionate growth of the nervous and skeletal systems (Mellanby, 1940; Wolbach and Bessey, 1941). The cranial and spinal cavities are underdeveloped and overcrowded.

Lathyrism, a few cases of which I saw in Syria, has also not been clearly related to deficiency of this vitamin, and there is some doubt about the nature of follicular hyperkeratosis and its deficiency ætiology (Stannus, 1945).

Vitamin-B complex.—Here we are on surer ground. I shall not go into the controversial aspects of the experimental evidence which indicates that some factors, at least, of the vitamin-B complex, are necessary for the normal activity of the central and peripheral nervous system. Chronic mild thiamine deficiency can give rise to degeneration of peripheral nerves (Swank *et al.*, 1940, 1941, 1942) in animals. Reduction of visual acuity (Peters, 1934, Marchesini, 1935) and deafness (Selfridge, 1937, Covell and Noble, 1937, and Covell, 1940) with degeneration of the optic and cochlear nerves has been demonstrated in thiamine deficiency. The posterior columns of the spinal cord may be affected (Zimmerman, 1941) and lesions identical with those found in Wernicke's encephalopathy can be produced with significant regularity by thiamine deficiency (Prickett, 1934; Alexander *et al.*, 1938, 1940) in pigeons, fish and foxes. In man experimental thiamine deficiency (Williams *et al.*, 1939, 1940, 1941 and 1943) produces a condition of a "neurasthenic" kind with but little evidence of polyneuritis, but in some cases flaccid weakness of the leg muscles and loss of the knee-jerks may develop and painful sensory disturbances in the lower limbs may be manifest (Jolliffe *et al.*, 1939).

Deficiency of riboflavine in experimental animals produces symptoms and signs, which as in the case of thiamine, vary according to the acuteness of chronicity of the condition. Acute deficiency produces collapse, after an interval of 100 to 150 days in dogs, and death will result if there is not prompt administration of the vitamin. These animals fail to show definite neurological lesions of a specific nature. In chronic deficiency there is ataxia and loss of tendon-jerks and at post-mortem there is degeneration of peripheral nerves and of the posterior columns of the cord (Sebrell *et al.*, 1937, 1938; Zimmerman *et al.*, 1941; Phillips and Engel, 1938; Lightner and Forbus, 1940, and others).

Isolated nicotinic acid deficiency in animals has been little studied but spinal cord lesions of moderate degree have been observed (Zimmerman, 1941). In pyridoxine B_6 deficiency severe anaemia and epileptiform attacks have been described and there are degenerative changes in the peripheral nerves and posterior columns of the cord (Wintrobe *et al.*, 1938, 1942 and others). Pantothenic acid is thought to be essential in the preservation of the spinal cord in chicks (Phillips and Engel, 1939). However, there are no indications that similar disturbances arise in man as a result of deficiency of pyridoxine or pantothenic acid.

There is plenty of clinical evidence which indicates that lack of the B complex, in whole or in part, leads to disturbances of the nervous system.

Retrolubar neuritis is found in pellagra, beriberi and in association with ariboflavinosis. Of 57 British P.S.O.W. from the Far East whom I have recently seen, no less than 45 had had beriberi. There were complaints of loss of vision in 35 (not due to refractive errors) and in 17 there were residual central scotomata. In Japan, retrolubar neuritis in men is nearly always seen in association with mild chronic beriberi, rarely in the acute form. In women it is almost invariably associated with lactation (Kagawa, 1938). There is a Japanese proverb which advises lactating women against sewing with a needle as it is a strain on the eyes at such times. Kagawa mentions a type of case seen in Japan, among individuals who have had several attacks of beriberi, in which retrolubar neuritis, nerve deafness and tinnitus, and ataxia are combined. He thought they were a special form of beriberi, in which peripheral paralysis was largely replaced by sensory ataxia. Thiamine cured them if the condition was not chronic. Retrolubar neuritis is also found in Wernicke's encephalopathy, and in hyperemesis gravidarum, with or without polyneuritic or encephalopathic signs.

Deafness is uncommon in beriberi but is mentioned by many of the older writers as occurring frequently in pellagra. It has been noted in patients suffering from

chemists that thiamine is concerned with the metabolism of the nervous system. The relief afforded by thiamine of the opisthotonus of the B₁ deficient pigeon is explicable only on the basis of a reversible biochemical lesion. But no such state has been observed in human polyneuritis. Acute beriberi in the infant and adult is essentially a cardiac disturbance. But that dramatic recovery from acute lower motor neurone paralysis *can* occur in man is well shown in the instances of tick paralysis following removal of the tick, and in myasthenia gravis and periodic paralysis on the administration of prostigmin or potassium respectively. Here we have evidence of reversible biochemical disturbances affecting the nervous system. But in human polyneuritis dramatic recovery does not occur and the pathological evidence points, not to the nerve cell or neuromuscular endplate, but to the peripheral axone as the site of injury. If a biochemical disturbance resulting from B₁ deficiency were the cause of polyneuritis should we not be justified in expecting better results than are generally achieved by the use of thiamine? One can only conclude that the relationship between the *biochemical* lesion of experimental B₁ deficiency and the *morphological* lesions of polyneuritis has yet to be demonstrated.

Perhaps we should recall the analogy made many years ago by Wright (1903) when he pointed out how misleading would be our conception of diphtheria if we based our studies of its pathology on post-diphtheritic polyneuritis. Most accounts of the pathology of beriberi are based mainly on chronic beriberic polyneuritis—which may well be in the nature of a residual phenomenon. Beriberi is certainly much more than polyneuritis and to consider these diseases as identical—with alcohol, white bread and breakfast cereals playing the role in the West that is taken by rice in the East—is a conception which is not altogether satisfactory.

A NEUROLOGICAL SYNDROME IN PRISONERS OF WAR

A neurological syndrome appeared in a German P.O.W. camp in the Canal Zone and the condition also occurred in other camps, in one of which it was widespread. The German camp housed soldiers of the Afrika Korps who were captured after the Battle of Alamein. Dysentery, infective hepatitis, malnutrition, œdema of the limbs were common among them at the time of capture. Many developed polyneuritis and an outbreak of pellagra occurred in the camp in December 1942. Thereafter pellagra was uncommon and beriberi did not arise. The mucocutaneous manifestations of riboflavin deficiency were not commonly observed. Diarrhœa and dysentery, however, remained a source of trouble during the next three years. In August 1943 the first cases of the neurological syndrome began to appear. They cropped up—a few each month—until, by January 1945, there were over a 100 at this camp. The distinctive features of the syndrome were retrobulbar neuritis, nerve deafness and ataxia. Other disturbances were laryngeal paresis, trigeminal hypoalgesia, loss of the senses of taste and smell, a mild secondary anaemia and reduction of free gastric HCl. Some cases showed cutaneous lesions of the lower limbs of the type known as follicular hyperkeratosis. But these disturbances were not common. More than half the total number of cases developed the ocular manifestations only—failing vision, central scotomata and, eventually, pallor of the optic discs. In about 20% there was some reduction of hearing, a few were very deaf. Painful dysesthesia of the lower limbs was a striking complaint in about 30%; half of these became ataxic. In such cases there was gross disturbance of stance and gait, retention of almost normal power in the legs, exaggerated tendon reflexes and loss of deep sensibility. In a few long-standing cases the ankle-jerks were reduced or lost and there were signs of slight involvement of the peripheral nerves. Superficial sensory loss was never marked and at no time were extensor plantar responses observed. The abdominal reflexes remained brisk and the arms were rarely affected. Outwardly, with a few exceptions, these men looked quite fit. By ordinary standards one would not have said they were malnourished, but I satisfied myself that their rations were seriously defective and that failures of supply, the substitution of alternative items of low vitamin content and primitive cooking arrangements were largely responsible for the deficiencies. Chronic diarrhœa, which was widespread in the camp, no doubt aggravated the condition.

One important case was that of a man who went ill with an attack of generalized œdema. A few weeks later he developed the typical picture of Wernicke's encephalopathy and responded quite remarkably to thiamine intramuscularly. But he was left with retrobulbar neuritis, nerve deafness, altered voice and ataxia. He actually developed a marked degree of polyneuritis when on treatment. I understand similar cases of Wernicke's syndrome have been observed in British P's.O.W. in the Far East, many of whom died and at post-mortem showed the characteristic brain-stem lesions. I have seen some of those who probably developed this syndrome in the East and who have residual signs of polyneuritis with or without visual reduction from retrobulbar neuritis. Wernicke's syndrome has not figured in the accounts of vitamin-B deficiency states described in Japan and elsewhere in the Far East, but Tanaka in 1943 came to the conclusion, from clinical and pathological investigation, that so-called breast-milk intoxication in Japanese infants was

none other than acute Wernicke's encephalopathy. Some authorities consider that breast-milk intoxication is a special variety of infantile beriberi.

In the German cases pellagra and ariboflavinosis were *not* present when they were under observation and only a few gave a history of such affections. Treatment was largely unsuccessful in clearing up the neurological signs. There was subjective improvement but the number which showed objective relief was small. Yeast, liver, nicotinic acid, riboflavine and thiamine were freely used for long periods.

ÆTIOLOGY

Vitamin A.—It has not been shown that vitamin A is concerned with the functioning of the nervous system. The nervous lesions in growing animals deprived of the vitamin are mechanical in origin. Lathyrism, a few cases of which I saw in Syria, has also not been clearly related to deficiency of this vitamin, and there is some doubt about the nature of follicular hyperkeratosis and its deficiency ætiology (Stannus, 1945).

Vitamin-B complex.—Here we are on surer ground. I shall not go into the controversial aspects of the experimental evidence which indicates that some factors, at least, of the vitamin-B complex, are necessary for the normal activity of the central and peripheral nervous system. Chronic mild thiamine deficiency can give rise to degeneration of peripheral nerves (Swank *et al.*, 1940, 1941, 1942) in animals. Reduction of visual acuity (Peters, 1934, Marchesini, 1935) and deafness (Selfridge, 1937, Covell and Noble, 1937, and Covell, 1940) with degeneration of the optic and cochlear nerves has been demonstrated in thiamine deficiency. The posterior columns of the spinal cord may be affected (Zimmerman, 1941) and lesions identical with those found in Wernicke's encephalopathy can be produced with significant regularity by thiamine deficiency (Prickett, 1934; Alexander *et al.*, 1938, 1940) in pigeons, fish and foxes. In man experimental thiamine deficiency (Williams *et al.*, 1939, 1940, 1941 and 1943) produces a condition of a "neurasthenic" kind with but little evidence of polyneuritis, but in some cases flaccid weakness of the leg muscles and loss of the knee-jerks may develop and painful sensory disturbances in the lower limbs may be manifest (Jolliffe *et al.*, 1939).

Deficiency of riboflavine in experimental animals produces symptoms and signs, which as in the case of thiamine, vary according to the acuteness of chronicity of the condition. Acute deficiency produces collapse, after an interval of 100 to 150 days in dogs, and death will result if there is not prompt administration of the vitamin. These animals fail to show definite neurological lesions of a specific nature. In chronic deficiency there is ataxia and loss of tendon-jerks and at post-mortem there is degeneration of peripheral nerves and of the posterior columns of the cord (Sebrell *et al.*, 1937, 1938; Zimmerman *et al.*, 1941; Phillips and Engel, 1938; Lightner and Forbus, 1940, and others).

Isolated nicotinic acid deficiency in animals has been little studied but spinal cord lesions of moderate degree have been observed (Zimmerman, 1941). In pyridoxine B_6 deficiency severe anæmia and epileptiform attacks have been described and there are degenerative changes in the peripheral nerves and posterior columns of the cord (Wintrobe *et al.*, 1938, 1942 and others). Pantothenic acid is thought to be essential in the preservation of the spinal cord in chicks (Phillips and Engel, 1939). However, there are no indications that similar disturbances arise in man as a result of deficiency of pyridoxine or pantothenic acid.

There is plenty of clinical evidence which indicates that lack of the B complex, in whole or in part, leads to disturbances of the nervous system.

Retrolubar neuritis is found in pellagra, beriberi and in association with ariboflavinosis. Of 57 British P's.O.W. from the Far East whom I have recently seen, no less than 45 had had beriberi. There were complaints of loss of vision in 35 (not due to refractive errors) and in 17 there were residual central scotomata. In Japan, retrolubar neuritis in men is nearly always seen in association with mild chronic beriberi, rarely in the acute form. In women it is almost invariably associated with lactation (Kagawa, 1938). There is a Japanese proverb which advises lactating women against sewing with a needle as it is a strain on the eyes at such times. Kagawa mentions a type of case seen in Japan, among individuals who have had several attacks of beriberi, in which retrolubar neuritis, nerve deafness and tinnitus, and ataxia are combined. He thought they were a special form of beriberi, in which peripheral paralysis was largely replaced by sensory ataxia. Thiamine cured them if the condition was not chronic. Retrolubar neuritis is also found in Wernicke's encephalopathy, and in hyperemesis gravidarum, with or without polyneuritic or encephalopathic signs.

Deafness is uncommon in beriberi but is mentioned by many of the older writers as occurring frequently in pellagra. It has been noted in patients suffering from

so-called acute nicotinic acid deficiency encephalopathy and in the polyneuritis associated with pregnancy.

A hoarse, weak voice is rare in pellagra but very common in beriberi. In the infantile form it is said to be pathognomonic and on many occasions has been shown to be due to recurrent laryngeal nerve paralysis; others attribute it to oedema of the larynx. In acute polyneuritic beriberi of adults it has also been observed (Jacob Bontius described it in 1645) and many prisoners of war in the Far East were so affected. Nine of my patients lost their voice during severe bouts of beriberi and many had hoarse weak voices for six months or more. A few have permanent changes. This disturbance has also been noted in association with polyneuritis during pregnancy.

Stannus (1944) has drawn attention to the possibility of deficiency of riboflavin or some allied substance as of aetiological significance in these nutritional affections of the nervous system. They have frequently been noticed in association with the mucocutaneous manifestations of riboflavin deficiency, with and without coexistent signs of nicotinic acid deficiency. It was interesting to learn that scrotal dermatitis due probably to riboflavin deficiency was very common among the P.O.W. group from the Far East. 46 out of 57 of my cases had intolerable itching, weeping and sometimes excoriation of the scrotum.

These random observations serve to indicate the complexity of the problem as to which particular member of the B complex is largely concerned with the production of these disturbances. It is very easy to follow only one track and perhaps no useful purpose is served in any attempt to classify them on the basis of existing knowledge. Some of these lesions were noted by the older pellagrologists in that hybrid affection we call pellagra. Even the recent accounts of acute nicotinic acid deficiency encephalopathy read very similarly to some of the old accounts of "typhoid pellagra". As Lombroso said of pellagra, "There is no disease, only the diseased".

A Central Nervous Deficiency Syndrome

By HUGH G. GARLAND, T.D., M.D., F.R.C.P.

IN February 1942 a number of British and Indian troops were captured by the Japanese and interned in Rangoon Gaol. They were released in April 1945 and, after rapid medical examination in India, were returned home. It was not at first appreciated that a number of these men showed an interesting neurological syndrome, but eventually I had the opportunity of examining 8 such cases. Later in the year Spillane and Scott (1945) recorded a series of 107 cases of a similar nature recognized by them in the Middle East in 1944, these being German prisoners.

After being incarcerated for a period, which in my cases was not less than eight months, defects of vision, hearing and gait develop. Of these the defect of vision is the only constant feature, commencing with failing vision, particularly near vision, which increases for weeks or months and then remains stationary, no case proceeding to complete blindness. Examination at this stage shows a very striking bitemporal pallor of the optic disc in most cases, and probably in every case there is some defect

of central vision. This defect is usually only demonstrable on a 2-meter screen, ordinary perimetry often showing no abnormality. The scotomata are central or paracentral, relative or absolute, for white or for colour. The defect of hearing consists of bilateral nerve deafness with or without tinnitus and, though sometimes severe, never proceeding to complete deafness. Symptoms referable to the spinal cord consist of numbness and tingling in the legs, rarely in the hands, and in the more severe cases unsteadiness of gait. The most constant objective finding is loss of vibration sense, frequently from the pelvis downwards, and in some there is loss of postural sense in the toes. There are considerable variations in the knee and ankle jerks, some being brisk, others absent. In one of my cases there were double extensor responses and in two others the plantar responses were equivocal. These are the essential features of the syndrome, though Spillane and Scott also noted laryngeal palsies and mental deterioration. In one of my cases, the most severe in all respects, there was intellectual deterioration with behaviour disorders. Within the past week, through the kindness of Mr. George Black, I have seen two further cases; one of these had also been in Rangoon Gaol and the other had been interned for a similar period in Hong Kong. Of the 10 cases I have examined, 6 were English, 1 Anglo-Burmese, and 3 Indian (2 Churkas and 1 Rajput). Vision was affected in all cases; the spinal cord in 6 and hearing in 4. All these 10 had been essentially on the same diet, and all had lost two or more stones in weight. In no case was there any history of glossitis, angular stomatitis, or scrotal dermatitis nor had any of them suffered from malaria, dysentery or other notable disease. Further investigation gave largely negative results, in all cases the spinal fluid being normal, gastric secretion being within normal limits, and the blood picture showing nothing more than a simple anaemia with eosinophilia, no doubt associated with hookworm infestation, which was present in them all. All these features have already been described by several authors and the only new clinical observation I made was that of continuous and rapid nystagmus in one man.

It would seem a reasonable assumption, requiring no further discussion, that this disorder is neither hereditary nor infective, but is almost certainly degenerative. Two factors might underlie such a degenerative process; one a toxin, such as that which causes lathyrism, the other some dietary deficiency. The toxic theory can, I think, be dismissed as being highly improbable in view of the fact that the syndrome has been observed in a wide variety of races scattered over Europe and Asia. Although most of the recorded cases have occurred in prisoners, the only feature common to all is that the victims have been living for a long period on a deficient diet.

Spillane and Scott considered the possibility of their cases resulting from alcohol, but this can be ruled out in my series as not one of these cases had taken alcohol in any form during the relevant period. Their final conclusion was that they were dealing with a nutritional neuropathy, the exact factor responsible being unknown. Unfortunately Spillane and Scott were only able to say what their cases should have been eating, and made no reference to what they did in fact eat, either in terms of calories or of the type of food. The diet their cases should have received was of a standard that, Dr. F. C. Happold tells me, was achieved by few people in this country throughout the war, with the possible exception of a few workers in the heaviest industries. That the cases of Spillane and Scott were not receiving the dietary laid down is implicit in the fact that from the camp in which cases had developed their neuropathy there were large numbers of cases of scurvy, beriberi and pellagra. I am more fortunately placed in that I know, more or less exactly, what my patients were eating. During the whole period they were given no bread, milk or butter. The basis of their diet was parboiled rice, about three-quarters of a pound per day, served in two or three meals. Meat was limited to two small pieces per week, the meat being very lean and often decomposed. It was usually buffalo, sometimes beef, and occasionally pork, but in all cases it contained practically no fat. Vegetables were eaten two or three times a week in the form of pumpkin, marrow, cabbage and chrysanthemum leaves, with occasional onions. Most of them received the grains dhal or gram daily and these, as with all the vegetables, were boiled. Small quantities of boiled sweet potato were served daily. During the first year limes or a banana were issued once a week and for the greater part of the time raw cucumber was available. The average egg ration was one or two a month. There was a small ration of tea and sugar, and the salt intake was adequate. Some of the men were able to smoke cheroots, but this was inconstant and in no case excessive. My first impression was that this diet might be deficient in vitamin A, as it contained little animal fat and the green vegetables, such as cabbage and chrysanthemum leaves, that were issued, were usually more yellow than green and often several days old. I was also reminded of the work of Mellanby (1931) in which an almost identical syndrome was produced in young animals living on a diet deficient in vitamin A only. It is now, however, thought that the neural changes in these animals resulted from the pressure of hypertrophied bone. Dr. Happold has studied the diet I have described and feels that vitamins A, B₁,

so-called acute nicotinic acid deficiency encephalopathy and in the polyneuritis associated with pregnancy.

A hoarse, weak voice is rare in pellagra but very common in beriberi. In the infantile form it is said to be pathognomonic and on many occasions has been shown to be due to recurrent laryngeal nerve paralysis; others attribute it to oedema of the larynx. In acute polyneuritic beriberi of adults it has also been observed (Jacob Bontius described it in 1645) and many prisoners of war in the Far East were so affected. Nine of my patients lost their voice during severe bouts of beriberi and many had hoarse weak voices for six months or more. A few have permanent changes. This disturbance has also been noted in association with polyneuritis during pregnancy.

Stannus (1944) has drawn attention to the possibility of deficiency of riboflavine or some allied substance as of aetiological significance in these nutritional affections of the nervous system. They have frequently been noticed in association with the mucocutaneous manifestations of riboflavine deficiency, with and without coexistent signs of nicotinic acid deficiency. It was interesting to learn that scrotal dermatitis due probably to riboflavine deficiency was very common among the P.O.W. group from the Far East. 46 out of 57 of my cases had intolerable itching, weeping and sometimes excoriation of the scrotum.

These random observations serve to indicate the complexity of the problem as to which particular member of the B complex is largely concerned with the production of these disturbances. It is very easy to follow only one track and perhaps no useful purpose is served in any attempt to classify them on the basis of existing knowledge. Some of these lesions were noted by the older pellagrologists in that hybrid affection we call pellagra. Even the recent accounts of acute nicotinic acid deficiency encephalopathy read very similarly to some of the old accounts of "typhoid pellagra". As Lombroso said of pellagra, "There is no disease, only the diseased".

[December 7, 1945]

Sepsis and Asepsis in Spinal Analgesia

By FRANKIS T. EVANS, M.B., D.A.

SPINAL analgesia has its place in anæsthetics, and under certain conditions is the method of preference. Though meningitis has occurred on certain occasions following its use, let us remember that many, many thousand spinal anæsthetics have been given without incident. During the twenty years I have been at Bart's Hospital I have not known of any case of meningitis in that hospital following spinal anæsthesia. Similarly, during the ten years I have been at St. Mark's Hospital there has been no meningitis in 2,500 spinal anæsthetics.

To condemn a useful and well-trying method because of a small proportion of unfortunate happenings in a vast total of cases is wrong. Yet we should inquire into those cases in which sepsis has occurred and endeavour to discover the cause. This is no easy task, for the reaction varies, from the so-called aseptic meningitis in which no organisms have been demonstrated, to a frank purulent meningitis due to a proven organism. Some of the meningitis cases recorded have shown some very unwelcome symptoms in that they have been prone to relapse.

There are many points at which the technique of spinal puncture can break down. In the past the methods of sterilization of apparatus have varied enormously, and this question of sterilization is of more than technical interest, for it has now a medico-legal aspect.

A report has recently been issued through a committee appointed by the Medical Research Council with regard to the sterilization of syringes. This committee consists of men whose opinions and recommendations carry weight. It is possible that a practitioner might be faced with this report by cross-examining counsel, and he might well find himself in an awkward predicament if his apparatus had not been sterilized in accordance with the recommendations laid down in this report.

Sepsis can enter the spinal canal as a result of spinal puncture:

- (1) From the hands of the anæsthetist.
- (2) From the skin of the lumbar area.
- (3) From the imperfect sterilization of syringes and needles.
- (4) From contamination of needles and syringes, which may occur through: (a) Infection from imperfectly sterilized towels; (b) Infection from so-called sterile water or sterile distilled water; (c) Infection from the local anæsthetic solution—novocain; (d) Infection from the spinal drug.

(5) Infection may also occur from hæmatoma due to repeated attempts at spinal puncture. Mr. Rogers tells me of cases within his knowledge where sepsis occurred as a result of hæmatoma due to repeated attempts at spinal puncture. A younger colleague has given me particulars of one case when a certain assistant anæsthetist was deputed to perform a spinal anæsthetic. He made several attempts to enter the spinal canal but failed. His chief then arrived and performed lumbar puncture at the first attempt in the space above. At the site of the assistant anæsthetist's many punctures, the patient subsequently developed an extradural abscess which spread subdurally. The patient died of meningomyelitis due to *Staphylococcus aureus*. The apparatus used for the puncture by both anæsthetists was autoclaved. It is significant that the assistant anæsthetist did not wear gloves.

With regard to the hands of the anæsthetist, I know that it is possible to perform a lumbar puncture without scrubbing up, and that it is equally possible to put on a pair of sterile rubber gloves without washing up and without contaminating the gloves. But the wisest course is to scrub the hands with soap under running water, just as one would do for any other surgical operation. The hands should then be well rinsed in 95% or 70% spirit, preferably for two minutes, and be allowed to dry. If the spirit is not allowed to evaporate from the hands, they should be dried with a sterile towel. Furthermore, I would recommend the use of sterile rubber gloves put on in the proper manner. If all these precautions are observed, the anæsthetist may be pretty sure that no infection can be conveyed from his own hands.

Skin preparation.—Obviously, no one would perform a spinal if the skin of the lumbar area were covered with acne or any infectious skin lesion. Professor Garrod

riboflavine and ascorbic acid, would be present in adequate amounts, though the nicotinic acid content is doubtful owing to the unknown composition of the cereals.

An allied syndrome was well described by Landor and Pallister (1935) in civilian Chinese, Malays, and Indians, in gaol in Malay. In all their cases, the neuropathy was preceded by glossitis, angular stomatitis and scrotal dermatitis. They did not describe deafness. The number of affected persons varied from 2 to 7% of the inmates (the incidence in Rangoon Gaol was probably 5 to 10%); there was no evidence of beriberi in the prison and they attributed the disorder to deficiency of vitamin B₂, claiming that the early symptoms responded rapidly to marmite or yeast and more rapidly still to liver treatment. Among American internees in Manila Whitacre (1944) described paresthesia and difficulty in focusing the eyes, which he regarded as due to vitamin B₂ deficiency, but the clinical descriptions are inadequate and he may not be describing the same disorder. Wilkinson and King (1944) have observed a similar condition in the civilian population of Hong Kong in 1940, at a time when pellagra became prevalent for the first time; there was no evidence of glossitis or stomatitis, but they regarded it as due to a dietary deficiency, considered that it was a form of pellagra and claimed results from nicotinic acid treatment. The diet in their cases was almost identical with that of my patients. Adolph and others (1944) described visual failure in American civilian internees in Japanese hands; there were associated cases of beriberi and pellagra and they felt that there was no evidence of deficiency of vitamins A, C or D. They claimed some improvement from yeast, but thought that the syndrome could not be related to any specific defect of diet and claimed no results from thiamine, nicotinic acid or riboflavin. Similar cases were also observed amongst civilians during the Spanish civil war in 1937-38, and in the past few weeks many more cases have appeared in this country, following imprisonment in Singapore, Java, and other places.

Reviewing the recorded cases, the following features therefore emerge. A clear-cut neuropathy has developed in a variety of races, scattered over the Middle East, the Far East and Spain. Although most of the victims have been in prison, the one factor common to all groups has been a defective diet. Although in all cases vitamin intake must have been low, and in many cases classical syndromes of vitamin deficiency have co-existed, there is no clear proof that this disorder has resulted from deficiency of any known vitamin. There has almost certainly been no deficiency of vitamins C or D and probably not of A. In my own cases, as well as in some of the others, the neuropathy has developed in the complete absence of any of the classical symptoms associated with deficiencies of any of the known members of the B group. At the same time, the indications generally point to the B group as the probable source of deficiency, and it seems probable that the deficiency is to be found here and that it may even be a deficiency of some member of this group at present unknown. Stannus (1944) regarded this syndrome as being probably the result of hypo-riboflavinosis, but certainly in my cases there is little evidence to support this view. The observation of this syndrome is relatively new but it is probable that in the past it has been missed or mistaken for something else; for example, it may well account for cases of optic atrophy and other unusual findings which have from time to time been reported as variants of both beriberi and pellagra. My own cases had in fact been seen by several physicians and variously ascribed to neuro-syphilis or to optic atrophy possibly the result of tobacco. I have little doubt that the prison populations of the tropics contain many more examples of this deficiency, which can be by no means rare, and an examination of such communities probably offers the most helpful field for future research. In the meantime the number of affected ex-prisoners now in this country has probably reached hundreds, possibly thousands. At present there is no known therapy of proved value and it would appear probable that some of the changes are irreversible. At the same time therapeutic possibilities in long-standing cases are not yet exhausted. We are all familiar with the optic atrophy and failing vision which sometimes complicate subacute combined degeneration of the cord. Remarkable recovery of vision may occur following liver therapy in this condition, and the changes in the spinal cord in this disease are by no means irreversible. There appears to be varying degrees of improvement in hearing following the return to a normal diet, but I am not aware of any improvement in vision nor of any change in the spinal cord dysfunction. I feel that this neuropathy is a discovery of considerable importance, that it is probably quite independent of beriberi and of pellagra, and that further investigation of its aetiology should be carried out at the source.

My own preference for sterilizing all-glass syringes is boiling in distilled water in a small sterilizer, and I prefer to boil them myself and dish them up myself, picking them out of the sterilizer (which is fitted with a rising tray) with my gloved hands.

There are other possible ways in which infection may occur. I know of one case in which pyocyanus meningitis occurred, the only possible failure in technique apparently being that the trolley was not covered with a sterile mackintosh under the sterile towel. The towel became sodden with water when the syringes were dishd up and it is presumably possible that contamination arose through the towel.

The rinsing of spinal syringes with so-called sterile distilled water has caused several cases of meningitis. Wilson Smith, Professor of Bacteriology at Sheffield, examined the sterile distilled water of several hospitals. Of 223 examinations of cerebrospinal fluid and water he was able to grow water-borne non-pathogenic organisms from 89; and from sterile distilled water he could grow organisms after the bottle had been opened for a few hours. Cuthbert Dukes grew a pure culture of pyocyanus from a sample of cerebrospinal fluid sent for examination and from distilled water. The cerebrospinal fluid was otherwise normal, and the patient showed no sign of meningitis. The real culprit was discovered to be the sterile distilled water in which the syringe and needle had been rinsed before use. This water came from a winchester of sterile distilled water which had already been opened. The remedy is obvious: if you must rinse your syringe and needles in sterile distilled water, take it from a new bottle which has been freshly sterilized. Barrie (1941) was using water from a Berkefeld filter which was defective, and although the organisms grown from the water were non-pathogenic, nevertheless when they ceased rinsing their syringes in this water the outbreak of meningitis following spinal anaesthesia ceased.

I know of an outbreak of meningitis following spinal anaesthesia in which the infecting organism was *B. coli*. Pyocyanus and *Staphylococcus aureus* have been grown from the cerebrospinal fluid and from the local anaesthetic used. I have, however details of one case which occurred after spinal puncture, the infecting organism here being *Staphylococcus albus*. It is interesting to note that symptoms did not occur until nine days after the operation, when the patient complained of a slight headache and vague pains over the coccyx and sacrum on getting up. He became pyrexial next day, but there was no definite sign of disease although he was examined by a medical specialist three days later. Eventually he was lumbar punctured some four days after that, i.e. eighteen days after the operation. The fluid withdrawn was opalescent and showed a lymphocytosis. The culture proved sterile. The next day he developed meningeal signs and was lumbar punctured again, the culture again being sterile.

Two days after this the lumbar puncture produced a growth of *Staphylococcus albus* on culture. He died on the following day. By this time the cerebrospinal fluid showed polymorph cells as well as lymphocytes. Sulphadiazine proved ineffective although given intravenously in a continuous drip. At post-mortem the extradural space was filled with blood-stained purulent fluid. The subdural space contained a little thin, cloudy fluid, and the subarachnoid field had thick pale-yellow pus extending throughout the length of the cord, most marked at the lower end. The spinal cord appeared to be normal. It was interesting to note that although the dura had been punctured on three separate occasions there was only one puncture hole to be seen.

The technique of lumbar puncture in this case was as follows: all-glass syringes, kept separately and used only for spinal anaesthesia; Howard-Jones needles; all apparatus boiled for twenty minutes. The local anaesthetic was 2% novotox from a freshly autoclaved bottle. This same local anaesthetic was used for other patients on the same day with no ill-effects.

The two cases of pyocyanus meningitis which occurred in a certain hospital where I worked I have already published, but there are one or two interesting points with regard to them. First, they both died and it was only after some three days had elapsed that there was any suggestion that meningitis had been present. Both patients were drowsy and complained of headache and rigidity of the neck. Both died comparatively suddenly and the course of the illness was afebrile. In the one case there was a generalized meningitis with thick pus up to the base of the brain, but pyocyanus was present in the turbid cerebrospinal fluid. In the second case the picture was complicated by the fact that the patient had a large retroperitoneal hæmorrhage which I suspect was the real cause of death.

The technique employed with these two patients was as follows. The spinal syringes were of the Record type and were kept by themselves in industrial spirit and used solely for spinal analgesia. They were rinsed with sterile normal saline together with the needles, and the skin was prepared with iodine and spirit, the anaesthetist wearing gloves. The local anaesthetic in both instances was novocain from a rubber-capped

told me that *B. coli* and *B. welchii* had been cultivated from the lumbar skin (R. A. Shabter). He thinks that it is more than probable that the lumbar skin becomes contaminated from the anus as a result of wearing pyjamas. It is also possible for organisms to be carried in by the needle, either on the point or just inside the lumen of the point. For this reason some people recommend an introducer, like the Sise introducer. On the other hand, there is the possibility of the organisms being wiped off as the needle advances in the ligamentous structures.

The literature on skin sterilization is voluminous. Personally I like old friends, and I pin my faith to soap and water first, this being followed by tincture of iodine and then spirit. My authority for this is Professor Garrod in a personal communication, and the work done by Hatfield and Lockwood whose test methods were first class and who proved to their satisfaction that iodine and spirit were highly efficient. They performed a series of experiments which were both simple and ingenious. They tested a series of skin disinfectants and were disappointed with the efficacy of the mercury preparations. They found that 95% alcohol applied to the hands for two minutes after scrubbing with soap and water proved the most effective skin preparation for the hands of personnel, but that if this was too expensive 70% alcohol was almost as effective. Alcohol, unlike CTAB, is, of course, not affected by soap.

Hatfield and Lockwood also found that for disinfection of the patient's skin 3-5% tincture of iodine, allowed to dry and followed by alcohol, which in turn is allowed to evaporate, was superior to other methods, and for this reason I remain loyal to iodine and the industrial spirit.

Although it is possible for infection to be carried in from the surface layers of the skin, I believe that meningitis, when it occurs, is introduced through the lumen of the exploring needle owing to an error in technique.

Sterilization of syringes and needles.—The report from the committee appointed by the Medical Research Council, dealing with the sterilization of syringes, recommended that syringes for spinal analgesia be all-glass and not glass and metal, for in the latter type of syringe infected clot or organisms can lodge in the interstices of the cement into which it is very difficult for the sterilizing fluid to penetrate. This committee suggests that the best method of sterilization for needles and syringes is either by dry heat at 160°C. for one hour (the thermometer being near the syringes), or by autoclaving at 120°C. for twenty minutes at 15 to 20 lb. pressure. The former of these methods is definitely inimical to the Record syringe, and the second is often so, as the temperatures are such as to melt the cement. For this type of sterilization one must therefore have glass syringes.

For years I put my syringes, taken apart, together with the needles (run through with spirit) into ordinary industrial alcohol for some ten to fifteen minutes before use. Fortunately nothing went wrong. Then I took to keeping them in industrial spirit in an airtight case. I had no cases of meningitis, and I personally have been fortunate in that I have never had a case of meningitis. The reason, I think, was due to the fact that those syringes and needles were used for nothing but spinal punctures.

I have seen syringes taken from a jar of spirit and placed ready for spinal anaesthesia. In that jar were other syringes and needles used for exploring and for aspirating pus. This practice cannot be too strongly condemned. Only the other day I saw a nurse preparing a trolley for a spinal anaesthetic. She took a syringe from a jar of spirit in which were other syringes, one of which had only been returned to the spirit some five minutes earlier. She placed the syringe in a sterile bowl and then went to the tap and ran tap-water into the bowl in order to rinse out the spirit.

The Medical Research Council Committee tells us that 90% industrial spirit will kill organisms (according to their experiments) in twenty-two minutes, and that 70 to 75% alcohol kills vegetative organisms in a much shorter time. They agree to the use of this method where the other methods are impracticable. They suggest that all-glass syringes be used and that they be immersed in 70 to 75% spirit for five minutes. The spirit must be fresh. Apparently organisms are killed by spirit but not spores; hence the emphasis on fresh spirit. (To make 70 to 75% spirit take four parts of industrial alcohol and one part of water.)

The Medical Council state that if dry heat or autoclaving is not possible, then boiling for five minutes in water is reasonably safe. I would add to that and say boil for five minutes in distilled water, for if the water in which the syringes are boiled is alkaline there is a risk of precipitating the anaesthetic as its insoluble base. Needles, too, may be boiled, and if fitted with guards they do not lose their sharp points.

The use of boiling oil for sterilization of syringes, although reminiscent of Gilbert and Sullivan, is not recommended for syringes, as the results are not uniform, although this method is quite satisfactory for needles. Personally I dislike it as it is messy.

My own preference for sterilizing all-glass syringes is boiling in distilled water in a small sterilizer, and I prefer to boil them myself and dish them up myself, picking them out of the sterilizer (which is fitted with a rising tray) with my gloved hands.

There are other possible ways in which infection may occur. The technique of lumbar puncture in this case was as follows: all-glass syringes, kept separately and used only for spinal anæsthesia; Howard-Jones needles; all apparatus boiled for twenty minutes. The local anæsthetic was 2% novutox from a freshly autoclaved bottle. This same local anæsthetic was used for other patients on the same day with no ill-effects.

The two cases of pyocyanus meningitis which occurred in a certain hospital where I worked I have already published, but there are one or two interesting points with regard to them. First, they both died and it was only after some three days had elapsed that there was any suggestion that meningitis had been present. Both patients were drowsy and complained of headache and rigidity of the neck. Both died comparatively suddenly and the course of the illness was afebrile. In the one case there was a generalized meningitis with thick pus up to the base of the brain, but pyocyanus was present in the turbid cerebrospinal fluid. In the second case the picture was complicated by the fact that the patient had a large retroperitoneal hæmorrhage which I suspect was the real cause of death.

The technique employed with these two patients was as follows. The spinal syringes were of the Record type and were kept by themselves in industrial spirit and used solely for spinal analgesia. They were rinsed with sterile normal saline together with the needles, and the skin was prepared with iodine and spirit, the anæsthetist wearing gloves. The local anæsthetic in both instances was novocain from a rubber-capped

bottle, the rubber being wiped over with iodine and the local anæsthetic withdrawn through a puncture. The spirit, syringes, the saline, and an ampoule of nupercaine from the same batch proved sterile on culture. Unfortunately the local anæsthetic bottle had been thrown away. I have no proof therefore that the local anæsthetic bottle was infected, but I strongly suspect that this was the case.

Organisms—staphylococci and *B. coli*—have been grown from so-called self-sterilizing local anæsthetic solutions on more than one occasion. However, we cannot say in the two cases I described that the novocain was actually guilty, but we cannot acquit it.

Thus, infection may occur from the anæsthetic solution—the procaine for local infiltration. The rubber-capped bottles are a real menace, though it is comparatively easy to sterilize the rubber cap by keeping it moistened with 10% chloroxylenol placed on the pad in the plastic cap, i.e. the Berry type of bottle. Alternatively, the top may be wiped over with spirit and iodine before it is pierced. Furthermore, it is possible for the novocain to become infected as a result of a previous use of the bottle.

If novocain is to be used, I prefer it from an ampoule or freshly boiled that morning. On the other hand, my resident, Maidlow, used the nupercaine itself as the local anæsthetic. In spite of the high sugar content I have never seen any ill-effects from its use into or under the skin, though I have not used it in a large series of cases.

Lastly, the use of the spinal drug itself may be the source of infection, but having seen the way the spinal drugs are prepared and the care taken in sterilization both of the ampoules and of the drug itself, the likelihood of contamination with organisms is very small indeed. For example, after sealing, the ampoules are immersed in a coloured solution under pressure so that any leaking ampoule will show at once when removed from the fluid, for its contents will no longer be colourless.

There is one possible source of infection via the ampoule, and this was brought into prominence by Hewer. Paper labels have been used on ampoules as a wartime measure because it has not been possible to get the ampoule etched as in pre-war days. Ampoules kept in spirit retain these labels, but if taken from the spirit and placed in any aqueous solution the labels float off and it is possible for organisms which have been imprisoned under the label (and therefore not killed by the spirit) to be released and thus form a source of infection. Ampoules may be kept in 70% spirit or the outsides may be sterilized by immersion in formalin vapour for twenty-four hours. To make doubly sure, never touch the ampoule with the hands but hold it in a swab.

So much then for the ways in which the infection may occur from breakdowns in technique. Are there any others? Yes, there is some evidence in favour of "chemical meningitis", but I would not overstress this. I have seen the records of five cases of light nupercaine anæsthesia which exhibited headache and vomiting, with pleocytosis in the cerebrospinal fluid. The symptoms began from one to four hours after operation and persisted for thirty-six to forty-eight hours. No organisms were grown from the cerebrospinal fluid although that counts for little according to Smith and Smith and Kremer. However, it was found that the nupercaine was slightly on the acid side, pH 5. Livingstone and others described 2 cases in a series of 4,006 nupercaine anæsthesias in which there was an increase of lymphocytes and protein in the cerebrospinal fluid accompanying mild meningitic symptoms. Culture was sterile. Barker found increased white cells twenty-four hours after spinal stavaine, and Jason and others described a lymphocytosis in the cerebrospinal fluid twelve hours after novocain in 14 out of 31 cases.

Orkin, in a summary of 45,966 cases of spinal anæsthesia by 20 different people, gives an incidence of 0.26% aseptic meningitis. Spiller and Payne reported aseptic meningitis following lumbar puncture in an epileptic. Reynolds and Wilson reported three cases following lumbar puncture in patients who had previously been diagnosed as chronic encephalitis, cerebral syphilis, and frontal tumour respectively. Livingstone and others commented on 8 cases they had collected, in which the symptoms were fever, stiff neck, positive Kernig, stupor and delirium. Cerebrospinal fluid cells (lymphocytes and polymorphonuclear leucocytes) were increased; onset of symptoms from one to sixty hours after operation. The drugs were allocaine, neocaine, nupercaine, novocain, and procaine. Of 7 cases commented on by Livingstone, Wellman, Clarke and Lambros, 4 recovered five to twenty-two days later and 3 died.

Davis and others published results of high nupercaine concentration causing meningitis in dogs. Kremer mentions that too alkaline sulphadiazine and iodine oils for myelography have produced a reaction. Personally I do not think that because nothing is cultured from the cerebrospinal fluid the case should be labelled chemical meningitis. Smith has shown that special technique is required for growing organisms from the cerebrospinal fluid. It is not infrequently found that no organisms can be grown in the meningitis that occurs from open brain wounds. So that the chemical and aseptic meningitis theory must be treated with extreme caution.

Secondary meningitis is said to occur if a lumbar puncture is performed in bacteræmia. It was shown to be possible by Weed and others experimentally, and was confirmed by Remson. Pray's clinical experiences tend to disprove this theory.

But we are considering clean cases. My records refer to operations for hernia, interval appendicectomy, hysterectomy and so on. The infective theory is the only one which really concerns us. Although no organisms were grown from the cerebrospinal fluid in Barrie's cases, yet as soon as the water from the defective filter was stopped, there were no more cases of meningitis. Infection has been conveyed from the hands, or following multiple unsuccessful attempts at puncture, possibly from the patient's skin (*Staphylococcus albus*). Local anæsthetic has been proven to contain living organisms (*Staphylococcus aureus*, *B. coli* and ? *pyocyaneus*). Experiments were performed with a certain self-sterilizing anæsthetic solution, and it was found that staphylococci survived several hours, *B. coli* two to five hours and *B. megatherium* three days. 1:1,000 chlorocresol B.P.C. is recommended and used at Bart's for the local anæsthetic in rubber-capped bottles and appears to be satisfactory. Lastly, the sterile distilled water has proved to be anything but sterile after being once opened. We grew *B. pyocyaneus* from it at one hospital.

SPINAL PUNCTURE

May I now suggest a safe spinal technique?

The skin is prepared by washing with soap and water in the ward, followed by spirit, the back then being covered with a sterile towel. On arrival in the anæsthetic room the sterile towel is removed, and the lumbar area is painted first with iodine, which is left to dry, and then with spirit which in its turn is allowed to evaporate. The sterile towel with a hole in it is then applied.

The anæsthetist, wearing sterile rubber gloves, injects novocain, preferably from an ampoule, into the skin and then subcutaneously. All ampoules are held in sterile swabs, and a hole is made in the skin with a de Caux needle. The spinal needle is passed through this hole, and the stylet removed before the needle enters the depths of the interspinous ligament. All glass syringes and needles are boiled in distilled water.

I have stressed this question of aseptic technique as it is my opinion that when sepsis occurs in spinal analgesia it is conveyed through the lumen of the spinal needle owing to some avoidable failure in the anæsthetist's technique. See your syringes and needles boiled; then you will know that they are sterile. Boiling does not blunt needles if the points are protected. See that ampoules are kept in lysol and spirit, and even then avoid direct handling, and introduce the needle into the ampoule without touching the exterior.

I have seen syringes boiled in water which contained sodium bicarbonate, thus causing the spinal analgesic to fail. A colleague told me of something he once saw in a theatre. An anæsthetist dropped the spinal needle on to the floor, and not having another he picked it up, moved it about rapidly in the spirit for a few moments, and then completed his spinal puncture. The patient subsequently developed meningitis.

With proper technique spinal anæsthesia is safe and is the method of choice for certain operations. The risk of infection in spinal analgesia, if performed in suitable surroundings and with adequate precautionary technique, is negligible. But if there is any deviation from this, then infection can occur, sometimes with disastrous consequences.

[A short film, illustrating the points made by the lecturer, was then shown.]

Professor L. P. Garrod supported the view that so-called aseptic or chemical meningitis was usually due in fact to bacterial infection. The presence in cerebrospinal fluid of Gram-negative bacilli derived from un-sterile water might be missed if cultures were not incubated at a temperature below 37°C. He had seen a number of such cases, due almost certainly to the contamination of lumbar puncture needles or manometers by immersion in distilled water which was supposed to be sterile, and cultivated organisms of this type

bottle, the rubber being wiped over with iodine and the local anæsthetic withdrawn through a puncture. The spirit, syringes, the saline, and an ampoule of nupercaine from the same batch proved sterile on culture. Unfortunately the local anæsthetic bottle had been thrown away. I have no proof therefore that the local anæsthetic bottle was infected, but I strongly suspect that this was the case.

Organisms—staphylococci and *B. coli*—have been grown from so-called self-sterilizing local anæsthetic solutions on more than one occasion. However, we cannot say in the two cases I described that the novocain was actually guilty, but we cannot acquit it.

Thus, infection may occur from the anæsthetic solution—the procaine for local infiltration. The rubber-capped bottles are a real menace, though it is comparatively easy to sterilize the rubber cap by keeping it moistened with 10% chloroxylenol placed on the pad in the plastic cap, i.e. the Berry type of bottle. Alternatively, the top may be wiped over with spirit and iodine before it is pierced. Furthermore, it is possible for the novocain to become infected as a result of a previous use of the bottle.

If novocain is to be used, I prefer it from an ampoule or freshly boiled that morning. On the other hand, my resident, Maidlow, used the nupercaine itself as the local anæsthetic. In spite of the high sugar content I have never seen any ill-effects from its use into or under the skin, though I have not used it in a large series of cases.

Lastly, the use of the spinal drug itself *may* be the source of infection, but having seen the way the spinal drugs are prepared and the care taken in sterilization both of the ampoules and of the drug itself, the likelihood of contamination with organisms is very small indeed. For example, after sealing, the ampoules are immersed in a coloured solution under pressure so that any leaking ampoule will show at once when removed from the fluid, for its contents will no longer be colourless.

There is one possible source of infection via the ampoule, and this was brought into prominence by Hewer. Paper labels have been used on ampoules as a wartime measure because it has not been possible to get the ampoule etched as in pre-war days. Ampoules kept in spirit retain these labels, but if taken from the spirit and placed in any aqueous solution the labels float off and it is possible for organisms which have been imprisoned under the label (and therefore not killed by the spirit) to be released and thus form a source of infection. Ampoules may be kept in 70% spirit or the outsides may be sterilized by immersion in formalin vapour for twenty-four hours. To make doubly sure, never touch the ampoule with the hands but hold it in a swab.

So much then for the ways in which the infection *may* occur from breakdowns in technique. Are there any others? Yes, there is some evidence in favour of "chemical meningitis", but I would not overstress this. I have seen the records of five cases of light nupercaine anæsthesia which exhibited headache and vomiting, with pleocytosis in the cerebrospinal fluid. The symptoms began from one to four hours after operation and persisted for thirty-six to forty-eight hours. No organisms were grown from the cerebrospinal fluid although that counts for little according to Smith and Smith and Kremer. However, it was found that the nupercaine was slightly on the acid side, pH 5. Livingstone and others described 2 cases in a series of 4,006 nupercaine anæsthesias in which there was an increase of lymphocytes and protein in the cerebrospinal fluid accompanying mild meningitic symptoms. Culture was sterile. Barker found increased white cells twenty-four hours after spinal stavaine, and Jason and others described a lymphocytosis in the cerebrospinal fluid twelve hours after novocain in 14 out of 31 cases.

Orkin, in a summary of 45,966 cases of spinal anæsthesia by 20 different people, gives an incidence of 0.26% aseptic meningitis. Spiller and Payne reported aseptic meningitis following lumbar puncture in an epileptic. Reynolds and Wilson reported three cases following lumbar puncture in patients who had previously been diagnosed as chronic encephalitis, cerebral syphilis, and frontal tumour respectively. Livingstone and others commented on 8 cases they had collected, in which the symptoms were fever, stiff neck, positive Kernig, stupor and delirium. Cerebrospinal fluid cells (lymphocytes and polymorphonuclear leucocytes) were increased; onset of symptoms from one to sixty hours after operation. The drugs were allocaine, neocaine, nupercaine, novocain, and procaine. Of 7 cases commented on by Livingstone, Wellman, Clarke and Lambros, 4 recovered five to twenty-two days later and 3 died.

Davis and others published results of high nupercaine concentration causing meningitis in dogs. Kremer mentions that too alkaline sulphadiazine and iodine oils for myelography have produced a reaction. Personally I do not think that because nothing is cultured from the cerebrospinal fluid the case should be labelled chemical meningitis. Smith has shown that special technique is required for growing organisms from the cerebrospinal fluid. It is not infrequently found that no organisms can be grown in the meningitis that occurs from open brain wounds. So that the chemical and aseptic meningitis theory must be treated with extreme caution.

A Consideration of Uretero-Colic Union and Some Experiences in the Operation

PRESIDENT'S ADDRESS

By A. WILFRID ADAMS, M.S.

THE EVOLUTION OF URETERO-COLIC UNION

THIS procedure is not yet standardized and some allusion to its evolution may be interesting. Surgical attention was at first mainly focused on the valvular junction of the ureters with the bladder. This was thought to have a major rôle in preventing the ascent of sepsis to the kidneys and, accordingly, Maydl in 1896 transplanted the ureteric ends "en bloc" with the trigone into the rectum. G. R. Fowler (1898) pointed out that Maydl's method was fallacious because the efficacy of the uretero-vesical valve depends on the rise of tension in a closed cavity by contents pressing constantly on its walls, a condition

FIG. 1a.

FIG. 1b.

FIG. 1.—Implantation of ureters, after Fowler, 1898 (*Amer. J. med. Sci.*, **115**, 274).

- (a) Incision on anterior wall of the rectum, including serous and muscular coats. Mucous membrane exposed in a diamond-shaped area, and the edges of the incision retracted by thread retractors. The dotted line shows line of section of mucous membrane to form the tongue-shaped flap.
- (b) Tongue-shaped flap cut, turned up, and laid upon itself (doubled back). The ureters are placed with their obliquely cut ends lying upon the surface of the flap and secured by catgut sutures in the space in the upper half of the diamond.

which prevails in the bladder but is wanting in the colon. Instead, he preferred the manoeuvre invented about the same time by Krynski (1895) who laid the ureter between the mucosal and muscular layers prior to opening into the bowel lumen and so effected a valvular insertion of the ureter. Krynski cured a man with ectopia vesicæ thus and the patient was well eight months later. Fowler sought to improve on this by adding a flap of rectal mucosa to shield the ureteric orifices (fig. 1a and b). Stress is laid on this

from the cerebrospinal fluid of most of them. Water or saline could only be safely used in this way if it came from a freshly opened bottle which had been autoclaved: the common belief that water was necessarily sterile because it was distilled was completely mistaken. The whole practice of sterilizing or attempting to sterilize surgical equipment in disinfectants and "dishing it" up in water was unsatisfactory. Sterilization by heat was the only safe method, and an alternative to boiling which was preferable in many ways was the use of dry heat. Needles and syringes could be enclosed in glass tubes and sterilized in a dry oven; they were then ready for use at any time.

Dr. R. J. V. Pulvertaft recalled a long series of cases of sepsis following spinal anaesthesia, the largest number he had seen simultaneously in one hospital was seven. In addition to meningitis, osteomyelitis of vertebrae was twice encountered.

The great features of such infections were chronicity, relapse, and multiplicity of infecting organisms; the organisms were usually of faecal type, and proteus, pyocyanus, coliform and faecal streptococci often co-existed.

Defective syringe sterilization was undoubtedly responsible for most cases; in one series in which he had been interested the syringe was shared between the theatre and a thoracic surgery ward. However, the M.R.C. instructions for syringe sterilization were not applicable to glass-metal syringes and all-glass syringes were not obtainable at present in numbers. The chief risk of syringe contamination lay in assembling wet syringes with dirty hands.

He had tested many samples of spinal anaesthetics without finding one infected; but they were not bactericidal and contained no bacteriostatic agent. There was nothing in the containers he tested to show that the samples complied with the Therapeutic Substances Act; batch numbers were not given.

He believed, personally, that spinal anaesthetics caused meningeal irritation—aseptic meningitis. He had tested the C.S.F. from a long series of cases, twenty-four hours after anaesthesia, and found excess of globulin and some increase of cells as a rule. Either all the cases were infected with some organism he could not see or grow, or the anaesthetic was irritant; and the excess of globulin provided an excellent culture medium. C.S.F. was itself a good medium. However, as he had not incubated cultures at room temperatures it was possible that certain saprophytes were present. On the other hand, these tests were done in the Middle East where "room" temperatures exceeded incubator temperatures.

Dr. R. J. Minnitt thought it might be of interest to the meeting to record that at one hospital where he worked cerebral symptoms were observed in some cases after spinal analgesia, and on investigation it was found that the powder which had been used for the rubber gloves was not sterile.

Dr. Stephen Coffin said that he considered the paper excellent, as it had dealt with many things often considered unimportant; but that he noticed that Dr. Frankis Evans' remarks had been largely in relation to hospital routine. Dr. Coffin pointed out that a sterility technique in private practice was often more difficult to attain than in hospital, as instruments had to be no less sterile yet portable and readily available; and that boiling as a means of sterilization was often not easily carried out if the only sterilizer available was occupied by the surgeon's instruments. He felt that an efficient routine for private practice needed as careful consideration as Dr. Evans had given to that for hospital, and suggested that a syringe service (such as was mentioned in para XI of Medical Research Council War Memorandum No. 15 for hospitals) could and should be organised for private practice. He said that he believed ether, lightly applied, to be the best skin sterilizer.

Squadron Leader B. G. B. Lucas said that the operation of lumbar puncture should be done under as strict an aseptic technique as any neurosurgical operation. No effort should be spared to achieve this as the consequences of sepsis inside the theca were often severe and far-reaching. The most rational way of obtaining this end was by employing as strict a "no touch" technique as possible and using a spinal introducer. All instruments were autoclaved and kept dry. The site of injection was palpated with the gloved hand through a sterile towel and marked with some antiseptic dye. Over this spot a special towel was placed with a small hole in it through which the introducer was passed.

Dr. Rex Binning said that we had been putting up with syringes of indifferent quality for too long. For sterile water he had been in the habit of using an ampoule of the water supplied with the pentothal—a practice which sometimes incurred the anger of the theatre sister but seemed otherwise free from risk.

Dr. H. W. Loftus Dale pointed out that in the film shown, the spinal needle was used for the purpose of charging the syringe with the fluid and suggested that the use of a filling needle for this purpose was preferable in so much as it eliminated the chance of contamination by contact with the outside of ampoules and labels, the danger of contamination by the glue of which had already been stressed. He also pointed out that the use of an introducing needle eliminated the risk of carrying into the subdural space the small punched-out piece of skin which may be found if the stylet does not make a dead accurate fit in the bore of the lumbar puncture needle. The use of some of the solution used for the spinal as a local anaesthetic before lumbar puncture not only enabled one to see if chance alkali contamination of the nupercaine had taken place but was a handy source of a solution of known sterility; the 20 c.c. nupercaine ampoule allowed ample for this purpose.

Dr. Frankis Evans, in reply, stated that he welcomed criticism of the film, which had been prepared rather hurriedly. Dr. Loftus Dale's comment re using the spinal needle for filling the syringe from the ampoule was pertinent. Actually, the needle used for filling the syringe was not the needle used for the spinal puncture, although the film did not make this point clear. In replying to Dr. Stephen Coffin he said that in private practice he carried a small drum containing towels, swabs, syringes, needles, &c. already autoclaved.

A Consideration of Uretero-Colic Union and Some Experiences in the Operation

PRESIDENT'S ADDRESS

By A. WILFRID ADAMS, M.S.

THE EVOLUTION OF URETERO-COLIC UNION

THIS procedure is not yet standardized and some allusion to its evolution may be interesting. Surgical attention was at first mainly focused on the valvular junction of the ureters with the bladder. This was thought to have a major rôle in preventing the ascent of sepsis to the kidneys and, accordingly, Maydl in 1896 transplanted the ureteric ends 'en bloc' with the trigone into the rectum. G. R. Fowler (1898) pointed out that Maydl's method was fallacious because the efficacy of the uretero-vesical valve depends on the rise of tension in a closed cavity by contents pressing constantly on its walls, a condition

FIG. 1a.

FIG. 1b.

FIG. 1.—Implantation of ureters, after Fowler, 1898 (*Amer. J. med. Sci.*, x15, 274).

- (a) Incision on anterior wall of the rectum, including serous and muscular coats. Mucous membrane exposed in a diamond-shaped area, and the edges of the incision retracted by thread retractors. The dotted line shows line of section of mucous membrane to form the tongue-shaped flap.
- (b) Tongue-shaped flap cut, turned up, and laid upon itself (doubled back). The ureters are placed with their obliquely cut ends lying upon the surface of the flap and secured by catgut sutures in the space in the upper half of the diamond.

which prevails in the bladder but is wanting in the colon. Instead, he preferred the manoeuvre invented about the same time by Krynski (1895) who laid the ureter between the mucosal and muscular layers prior to opening into the bowel lumen and so effected a valvular insertion of the ureter. Krynski cured a man with ectopia vesicæ thus and the patient was well eight months later. Fowler sought to improve on this by adding a flap of rectal mucosa to shield the ureteric orifices (fig. 1a and b). Stress is laid on this

original operation of 1896 recently by R. S. Fowler (1943), who quotes: "Placing the ureters in the submucous space of the rectal wall for a distance of three or more centimetres about the point where these enter the cavity of the rectum affords an additional safeguard against renal infection." He (G. R. F.) reported the satisfactory state of his patient a few years later; but his procedure, like that of Maydl, failed to find favour among surgeons. The fear of renal pollution still dominated the medical mind until the description by Grey Turner (1929) of a large group of successes roused the hopes and expectations of the most sceptical. He had been using Stiles' (1911) method of union after the fashion of a Witzel's gastrostomy. In the interim Coffey (1921, 1928) published his method, which virtually was a slight variant of the Krynski principle and he developed the use of an indwelling ureteric catheter. But careful analysis casts some doubt on the competence of this barrier for, presumably, in the bowel wall the ureter is only flattened out momentarily as pressure rises with peristalsis squeezing faeces past the site; whereas into its patulous mouth fluid matter of the resting bowel may pass readily. The mucosal flap over the ureteric orifices devised by Fowler as a faecal guard is ingenious, but somewhat theoretical. The situation may, nevertheless, not be as hopeless as this criticism suggests, for, still fashioning a simple union, Grey Turner (1943) reports diminishing incidence of ascending renal sepsis. Nature, too, offers further deterrents to ascending infection, viz. the regular flushing of urine in the reverse direction, as well as contraction of the ureter by its own peristalsis. Fowler (R. S.) quotes from Dr. Vaper Branch in 1912: "... that reflux is prevented much more by the ureter itself than by the obliquity of its valve". Certainly the incidence of renal infection does not appear proportional to the degree of dilatation of the ureters prior to transplantation. Sir Henry Wade (1939) advocated simultaneous bilateral transplant. He relies on the routine transfusion of isotonic sod. sulph. to prevent anuria and, by flushing the ureters, to stem the ascent of faecal sepsis.

Urinary obstruction.—Other dangers have declared themselves and engaged much surgical thought and experimentation. Not only is ascent of faecal infection to be feared but the reverse, namely, impeded down-flow of urine. This may occur early from unduly tight stitching of the bowel wall, when burying the ureter, or from subsequent oedema. Later, stenosis may ensue owing to infection and necrosis of the ureteric end with subsequent granulation and scarring. I have endeavoured to contend with these risks by following Grey Turner's lead. He warmly advocates simplicity in technique and relies on gentleness and tactful stitching, whereas others, notably Coffey and recently Wharton (1942), preserve patency by an indwelling catheter in the ureter when stitching the bowel over it. The elaborate technique of the Coffey procedure contrasts sharply with the simplicity of Grey Turner's operation. Urinary obstruction is also liable from angulation and kinking of a redundant ureter as it approaches the colon; but equally dangerous would be tension or drag of the sigmoid loop on the junction. To meet with both these contingencies I surround the colon by four stitches which tie it to the upper end of the opening of the parietal peritoneum through which the ureter is brought. Any excess ureter finds harmless accommodation retroperitoneally where, in the course of routine pyelography, surprising bends and loops are sometimes seen and compatible with satisfactory function.

Blood supply.—Some allusion is merited to the blood reaching the free end of a long length of isolated ureter. Here the evidence of Hinman and Weyrauch (1942) is valuable, that "the end often sloughs level with the rectal mucosa, though not proximal unless in instances of massive necrosis. A cross circulation from the intestine lends added vitality to the ureter soon after the first week". Operation provides a practical test and suggests that, as little blood oozes from the raw ends, the circulation is somewhat precarious in the adult. It is well to remember that Stiles was reporting operations on infants when he wrote "the ureters possess such a rich blood supply that the danger of necrosis is probably no greater with the latter (Witzel) than with the former (Maydl) procedure". A feeble circulation is helped by gentle handling aided by parietal relaxation of spinal anaesthesia, which I routinely use, the elimination of indwelling catheters that might press on delicate vessels, and tactful stitching of colon when embedding the ureters. The patient's general circulatory tone is best supported by minimum interference with normal activities. In the ordinary patient an enema on the day prior to operation assures absence of faecal accumulation. More prolonged preparation is needed in the constipated.

Earlier operation in infancy.—Thus there emerge three chief objectives in the operation—secure fusion of the tubes, a pervious passage through the ureter and its adequate blood supply. At this juncture it is appropriate to allude to what is quite unorthodox teaching by Higgins (1943) who, using the Coffey method and fusing one ureter at a time, advocates operating on cases of congenital vesical incontinence in the first year instead of waiting till the child is five. His reasons are clearly set forth and make a strong appeal. He emphasizes the high death-rate from renal infection early in the life of the unoperated

FIG. 2a.

FIG. 2 (a and b).—Experimental transplantation of the ureters, after Ferguson (Military Surgeon, 1931, 69, 184).

FIG. 2b.

FIG. 3a.—Technique, after Winsbury-White, 1933 (*Proc. R. Soc. Med.*, 26, 1215).

FIG. 3b.—Technique, after Jewett, 1912 (*J. Urol.*, 48, 407).

and the exclusion of this cause of failure by intervening before the wonderful potentialities of the circulation in the early months of life are lost. In support of this claim is the astonishing successful healing that follows other operations on the most puny infants in the early weeks of life, e.g. for intestinal obstruction, jaundice and, even, a $1\frac{1}{2}$ lb. nephrectomy on a child of 10 weeks (Adams, 1937), who is now a bonny girl.

Widening Field of Operation

So much for the operation to cure the life-long misery of congenital incontinence. Deviation of the urine is, however, being practised for an increasing variety of ills and even in late adult life. Of course such operations carry with them great risks. For instance, the transfer of his urine to the colonic receptacle in the sickly subject of vesical cancer is certainly a hazardous undertaking and the results of Coffey's operation, collected in 1939 by Hinman (1939), are daunting—a mortality of about 50% in 132 such cases! From their earlier brilliant successes Morson and Graham (1940) describe 13 cases of mixed pathology treated by simple technique. They report that their deaths (5) were confined to "advanced malignant disease". B. J. Ward (1936) reports a series of 7 successful cases.

Two-stage operation.—Something more seems needed, and this Ferguson (1931) may have provided by his strategic approach to the problem. He saw that while the new structure was becoming soundly consolidated there was no need to involve it in new function, any more than we tread on concrete till it is dry. He planned the operation in two stages—*form first, function second*. He fused the intact ureters to the colon while leaving the urine still flowing to the bladder. The union having thus become sealed against the access of bowel infection and assured its vitality in the new site, the ureter may then, like a bridge-graft, safely be divided at the distal end, and the lumen of the uriniferous segment be opened into that of the attached colon (fig. 2). His success in the dog was followed by that of Winsbury White (1933) in the human (fig. 3a). Substantial experimental support was added by Vermooten (1934) who, referring to the one-stage method, "showed that a conspicuous cause of failure was the immediate accessibility of the freshly opened tissue spaces within the wall of the bowel to the pathogenic bacteria in its lumen. Exudate surrounding the embedded portion of the ureter was almost inevitable. If such animals survive, the organization of this periureteral exudate will produce a mechanical ureteral obstruction, and at the same time reduce the efficiency of the uretero-intestinal valve, or destroy it entirely".

The elaboration of the two-stage fusion in the human has been most thoroughly pursued by Jewett (1942, 1943). A month after bilateral fusion of the uncatheterized ureters to the colon, he applies diathermy by a special electrode to about a centimetre of the septum separating the interiors of the blended tubes, an elaboration of the principle depicted in fig. 2. A total cystectomy is combined with this functional coalescence. Great stress is laid on the need for strict alignment of colon and ureter, conspicuous in the illustration, to exclude kinking at the junction of the tubes (fig. 3b). He reported his results in 1942 and a further series in 1944. Intestinal adhesions were his chief complication and he gives a detailed description of the most meticulous ritual to avoid their formation. Experience has proved to him that the site of fusion can be steadied adequately by a few stitches uniting the upper and lower ends of the fusion line to the parietes and, dispensing with fixation by extra-peritonization, he has saved adhesions.

Illustrations from the earlier operation of Winsbury White and Jewett's latest technique make an interesting comparison. The former is so much simpler but I have no figures of a series done in that manner. Jewett's latest results in vesical cancer are most encouraging, only one patient having died out of the last ten and that was due to pulmonary metastases. Before closing this review of the history of uretero-colic fusion, two points in Wharton's single-stage modified Coffey operation call for remark. Piercing the colonic mucosa is apt to be an awkward little manoeuvre and seems more efficiently done, as he advises, with a cautery. But his main contribution is fixation of the colonic fusion site back to the pelvic wall in such a way that the ureter lies in its natural bed. This seems the best insurance of all against strain and kinking.

Peritonitis.—This has figured less in these remarks than might seem due in view of the risks of both urinary and faecal contamination or post-operative leakage. Doubtless the adhesive type follows in some degree more or less routinely, even after the simplest procedure; but in a grossly suppurative form it is remarkable for its rarity. It is likely to figure more prominently when operating for the relief of urinary cancers or tuberculosis. At the Middlesex Hospital recently, Mr. Riches showed us *retro-peritoneal anastomosis*. He delivered the bowel, then stitched the edge of the opening in the peritoneum around the area planned for ureteric union and to this joined the proximal

ureter. This appeals as a logical means of circumventing risks to the peritoneum, though I have found smooth alignment of the two tubes more difficult. He was content to deal with one ureter only at a session, which may not halve the hazards of healing but must appreciably reduce them; and one intact ureter offers a comfortable degree of life insurance, while a transplant is "taking" on the other side.

PERSONAL EXPERIENCES

In relating my own experience of uretero-colic union it seems well to group the cases on a pathological basis. From their discussion will be gleaned indications for the operation, their differential diagnosis, points in technique, after-care and progress.

To the oldest and obvious indication for transplant—ectopia vesicæ—reference has already been made in quoting Higgins' advocacy of earlier operation. My experiences chance to be small and unprofitable to quote; but here I should like to report a much rarer congenital defect—absence of urethra—in F. P., a girl aged 5 years. She had complete incontinence and might have tempted one to resort to ureteric transplantation. Instead I tried a simple plastic closure of the bladder neck and now, two years later, she has achieved good control by day and most nights.

In regard to acquired incontinence, I have one obstetric case to report. E. S., aged 29, came, still incontinent, after four attempts elsewhere to close a vesico-vaginal fistula of two and a half years' duration. The gynæcologist still objected to uretero-colonic anastomosis, fearing kidney sepsis, so I added my plastic effort to those of my predecessors and

FIG. 4a. Pyelography before (a) and after (b), uretero-colic union for obstetric fistula.

gained a good exposure in a fat woman by a preliminary removal of pubic bones. The repair of the fistula at the bladder neck seemed promising but, despite this and ureteric catheters remaining for four days, the fistula recurred.

On 21.4.44, after pyelography (fig. 4a) and a prescribed loss of three stone in weight, bilateral uretero-colonic anastomosis was done. Total cystectomy cured the prolapsing bladder on 2.6.44. The ureters were of normal size and the method of anastomosis was that used by Grey Turner and by me in most of my cases. Although on full work and urinating three-hourly, her skiagrams now show a stone in her left kidney (fig. 4b).

Refractory Ulcerative Cystitis

While the cause of this malady remains obscure, the perpetual agony and often the ostracisms suffered by its victims are painfully obvious and led me to try relief by dysfunctionating the bladder. Included in this group with four typical female cases are a few males whose complaints were bitter enough but in whom the cystitis is of somewhat obscure pathology.

The first story is that of A. S., aged 29, married. She came in 1942 with severe dysuria and sterile slight hæmaturia. The bladder was ulcerated irregularly in a crescentic zone near the dome. As the urogram portrayed, it was a contracted and intolerant organ even with spinal anaesthesia (fig. 5a). The routine simultaneous intra-peritoneal transplant was undertaken in September 1942. Irregular fever, which is not uncommon, followed in her case. There was a suspicion of swelling in both loins and she was troubled by

and the exclusion of this cause of failure by intervening before the wonderful potentialities of the circulation in the early months of life are lost. In support of this claim is the astonishing successful healing that follows other operations on the most puny infants in the early weeks of life, e.g. for intestinal obstruction, jaundice and, even, a $1\frac{1}{2}$ lb. nephrectomy on a child of 10 weeks (Adams, 1937), who is now a bonny girl.

Widening Field of Operation

So much for the operation to cure the life-long misery of congenital incontinence. Deviation of the urine is, however, being practised for an increasing variety of ills and even in late adult life. Of course such operations carry with them great risks. For instance, the transfer of his urine to the colonic receptacle in the sickly subject of vesical cancer is certainly a hazardous undertaking and the results of Coffey's operation, collected in 1939 by Hinman (1939), are daunting—a mortality of about 50% in 132 such cases! From their earlier brilliant successes Morson and Graham (1940) describe 13 cases of mixed pathology treated by simple technique. They report that their deaths (5) were confined to "advanced malignant disease". B. J. Ward (1936) reports a series of 7 successful cases.

Two-stage operation.—Something more seems needed, and this Ferguson (1931) may have provided by his strategic approach to the problem. He saw that while the new structure was becoming soundly consolidated there was no need to involve it in new function, any more than we tread on concrete till it is dry. He planned the operation in two stages—*form first, function second*. He fused the intact ureters to the colon while leaving the urine still flowing to the bladder. The union having thus become sealed against the access of bowel infection and assured its vitality in the new site, the ureter may then, like a bridge-graft, safely be divided at the distal end, and the lumen of the uriniferous segment be opened into that of the attached colon (fig. 2). His success in the dog was followed by that of Winsbury White (1933) in the human (fig. 3a). Substantial experimental support was added by Vermooten (1934) who, referring to the one-stage method, "showed that a conspicuous cause of failure was the immediate accessibility of the freshly opened tissue spaces within the wall of the bowel to the pathogenic bacteria in its lumen. Exudate surrounding the embedded portion of the ureter was almost inevitable. If such animals survive, the organization of this periureteral exudate will produce a mechanical ureteral obstruction, and at the same time reduce the efficiency of the uretero-intestinal valve, or destroy it entirely".

The elaboration of the two-stage fusion in the human has been most thoroughly pursued by Jewett (1942, 1943). A month after bilateral fusion of the uncatheterized ureters to the colon, he applies diathermy by a special electrode to about a centimetre of the septum separating the interiors of the blended tubes, an elaboration of the principle depicted in fig. 2. A total cystectomy is combined with this functional coalescence. Great stress is laid on the need for strict alignment of colon and ureter, conspicuous in the illustration, to exclude kinking at the junction of the tubes (fig. 3b). He reported his results in 1942 and a further series in 1944. Intestinal adhesions were his chief complication and he gives a detailed description of the most meticulous ritual to avoid their formation. Experience has proved to him that the site of fusion can be steadied adequately by a few stitches uniting the upper and lower ends of the fusion line to the parietes and, dispensing with fixation by extra-peritonization, he has saved adhesions.

Illustrations from the earlier operation of Winsbury White and Jewett's latest technique make an interesting comparison. The former is so much simpler but I have no figures of a series done in that manner. Jewett's latest results in vesical cancer are most encouraging, only one patient having died out of the last ten and that was due to pulmonary metastases. Before closing this review of the history of uretero-colic fusion, two points in Wharton's single-stage modified Coffey operation call for remark. Piercing the colonic mucosa is apt to be an awkward little manoeuvre and seems more efficiently done, as he advises, with a cautery. But his main contribution is fixation of the colonic fusion site back to the pelvic wall in such a way that the *ureter lies in its natural bed*. This seems the best insurance of all against strain and kinking.

Peritonitis.—This has figured less in these remarks than might seem due in view of the risks of both urinary and faecal contamination or post-operative leakage. Doubtless the adhesive type follows in some degree more or less routinely, even after the simplest procedure; but in a grossly suppurative form it is remarkable for its rarity. It is likely to figure more prominently when operating for the relief of urinary cancers or tuberculosis. At the Middlesex Hospital recently, Mr. Riches showed us *retro-peritoneal anastomosis*. He delivered the bowel, then stitched the edge of the opening in the peritoneum around the area planned for ureteric union and to this joined the proximal

natural despite its eventful history! The right uretero-colic union showed a satisfactory papilla on the bowel lumen but the left ureter ended abruptly and blindly at its junction with the serosa of the colon and had evidently undergone necrosis distal to this point. Function had been suppressed on that side where the ureter was dilated but the kidney unaffected. Obviously she had been living solely on the enlarged right kidney of which the ureter and pelvis were dilated and contained phosphatic aggregations—the source of her skiagraphic opacity—and a little muco-pus. There were merely moderate ileal adhesions to pelvic colon.

Reflection provokes the question, could this patient have been saved by early resort to uretero-colic union?

M. V., aged 24, married: She came in September 1944 with dysuria which had defied diagnosis and relief since causing her discharge from the Army a year before. Hers was a fitful history and started in childhood with urgent urination at inconvenient times. In her late teens nocturnal frequency set in and, in 1938, right renal pain. Later it came on the left and removal of that kidney was advised, but the trouble abated. She "joined up" and went to France in 1940. When urgent micturition recurred in 1943 she was put on her mettle as a case of "nerves". She tried to ignore it and took up cycling, but had to hop over the hedge too often to enjoy it! Micturition became painful and she so ill as to be mostly in bed from July to September 1943. After investigation "M & B" tablets improved her. Relapsing again in 1944 she was sent to me. I diagnosed refractory ulcerative cystitis and, as I foresaw a future of grave suffering and disability, advised diversion of the urine to the colon. The urines from both kidneys were healthy, although obvious hydro-ureter and hydronephrosis were manifest. The crescentic ragged ulceration above the ureteric orifices of a contracted bladder conformed better to refractory ulcerative cystitis than tuberculosis, and repeated search for organisms was negative. In September 1944 the routine transplantation was done of ureters dilated to the calibre of an average pencil. After the initial post-operative setback she made rapid strides and by the fourth week her urine was "clearer than before operation". She thrived well, put on weight and got her desire, joining her husband in West Africa in July 1945.

Among the males, R. P., aged 62, illustrates the efficacious result of unilateral diversion of the ureteric flow. In 1940 he came to me with a story of cystitis for ten years following catheterization for sudden retention. His frequency had become $\frac{D}{N} \frac{20}{10}$ and so agonizing that he was thrice found unconscious on the lavatory floor. The urine showed pus, *B. coli* and streptococci. There was a one-ounce hydronephrosis seen on the right and a normal left pyelogram. Cystoscopy showed a single, terraced, ovoid ulcer, about 2 cm. across, with deep necrotic base. It suggested Fenwick's solitary ulcer in the region of the right ureteric orifice. Guinea-pig tests of urine and a biopsy of the right ureter were negative for tubercle. After a preliminary cutaneous right ureterostomy and excluding cancer by palpation of the exposed thimble bladder, I turned the ureter into the ascending colon. Micturition soon became and remained normal. The intravenous pyelogram, five years later, is fair on the left but no dye is apparent on the right. In this remarkable case a bladder, the site of a refractory ulcer centring on a ureteric orifice and causing intense dysuria, was restored to normal function and the patient to full vigour by diversion of corresponding ureter to colon with consequent defunctionation of that uretero-vesical junction.

F. P., aged 57, is another case of inveterate, intensely painful cystitis but in which transplantation came too late. About the right third of his bladder showed leukoplakia, having a uniform icing-sugar appearance of sharp rounded outline when I first cystoscoped him in 1943. His past history included removal of testicle, which proved to be tuberculous in 1924, and since then pain in the right loin. In 1934 vesical instillation of calomel oil had eased cystitic symptoms till, in 1943, after right renal colic, he passed a small stone and since then pain had recurred. Nothing but a few *B. coli* were found in his urine. Lupus of bladder was considered but guinea-pig inoculation proved negative as did biopsy of the scarred right kidney which I found on exploration. I failed to catheterize the right ureter. Urine from the left was healthy. Pyelograms were fairly dense. By January 1945 there was added to the spectacular leukoplakia, general engorgement and ragged ulceration. Left extra-peritoneal transplant was done as a desperate measure but he died ten days later. The sketch of the specimen (Fig. 6) shows the very interesting ascent of the leukoplakia two inches up the right ureter where, as on the bladder mucosa, its outline was sharply demarcated. That kidney was grossly septic. The left kidney and ureter appeared clean, except at the anastomotic level where the lining was sloughing and a small abscess in the uretero-colic interval exuded pus into the ureter. It appeared well walled-off.

The final revelation rouses speculation regarding aetiology. Was not infection, possibly tuberculous, of the right kidney responsible for this obscure vesical lesion and the latter curable in its early history by nephrectomy; or, in the later stage, would not defunctionation of the bladder be the only hope?

W. W., aged 63, came with an intolerable cystitis of some five years' duration and I diagnosed a primary refractory ulcerative cystitis. The only way out of his misery appeared to be by the drastic remedy of defunctionating the bladder. I performed left uretero-colic union on 30.5.45, and was delighted with the prompt benefit. But his old symptoms are back again and diarrhoea in addition. I am deterred from completing the diversion of urine from the bladder with right ureteric transplant, which would seem the logical procedure, owing to a startling radiographic discovery—gross calcification in his prostate! This invalidates my original opinion, will probably alter the treatment and teaches the grave responsibility of infallible diagnosis before embarking on a profound and irrevocable transgression on the body.

another frequent post-operative discomfort—that of flatulent distension. This may be relieved by the regular passage of a flatus tube every four hours, which also prevents the accumulation of urine in the bowel during the first few days. When she visited the ward again three months later her much improved aspect disguised her identity from the ward Sister. Despite her clinical well-being, radiography, 10.3.43 (fig. 5b), reveals obvious dilatation of ureters and kidneys. The current picture is the same. She remains delighted, at full work and urination is usually only five-hourly and not at night but, with a cold, may be every two hours.

She recently asked: "May I have a child?" Her blood urea is 0.060% and her weight does not increase so I shall warn her of the risk. Many will recall Grey Turner's triumphant picture of a woman with the four children she bore after ureteric transplant.

Since the above was written she has died from a brief attack of uræmia, December 1945. Yet the post-mortem showed a reconstructed urinary system which was apparently satisfactory.

D. G. came first in 1937 at the age of 21. Repeated diathermy to a patch of ulceration in the fundus was ineffectual so, in 1938, I operated. Cystotomy cut the ulcer in twain. It was a discoid lesion, about two centimetres in diameter, raised like a button in the bladder wall the whole thickness of which was excised. The removal appeared complete and the pathologist reported "appearances agree with Hunner's elusive ulcer of the bladder". She resumed full work, looked radiantly healthy and lost her pain and frequency but, contrary to my advice, married in October 1939. Her symptoms at once returned and she became a social outcast. Cystoscopy confirmed the cystitis and healthy urines in the ureteric specimens. Pyelograms in 1937 had been normal but by 1943 showed marked hydro-ureters and renal dilatation. Pain in her loins and, finally, hæmaturia reconciled her to uretero-colic union in February 1943. Faced with mega-ureters I offered her a transplantation of one ureter at a time, but she would only consent to a single intervention. At this operation a technical difficulty declared itself in the

FIG. 5a.

FIG. 5b.

FIG. 5 (a and b).—A. S. Pyelography before (a) and after (b), uretero-colic union for refractory ulcerative cystitis.

tendency of a large ureter and the necessary enfolding of the colonic wall to encroach obstructively on the bowel lumen. Her convalescence was an anxious time with recurrent fever, headache, vomiting and pain and foul discharge on lavage of bladder. Urination was satisfactory and only once was tenderness in the right loin present.

The reward for effort came a year later when her husband wrote: "Everyone still cannot believe that my wife is enjoying such good health after suffering so long." In June 1945 urination was three to six times by day and once at night. She had done an ordinary wartime job for a year and was adopting an infant.

F. W., aged 44, told a like story of long, painful and incapacitating illness. Cystitis had already troubled her for two years when first I saw her in 1939, frail in form and voice and with a pale waxen countenance. Irregular ulcerous areas at the back of the bladder increased despite diathermy. It was in her case that one of the excavations was seen oozing blood during cystoscopy and the bladder ruptured into the peritoneum. She survived immediate laparotomy and, indeed, the result was surprising amelioration of symptoms but, later, she deteriorated and consented to the desperate uretero-colic union. This was preceded by pyelography, and precautionary sigmoidoscopy, as diarrhoea also had become a serious worry. The operation was on 9.8.44, and convalescence anxious, but she was gratified with her new "water-works" till terminal pyelonephritis developed this spring and urography showed a calculous cast of the right pelvis. She died on 9.6.45. Post-mortem showed the bladder lining smooth and shiny but the organ otherwise notably

natural despite its eventful history! The right uretero-colic union showed a satisfactory papilla on the bowel lumen but the left ureter ended abruptly and blindly at its junction with the serosa of the colon and had evidently undergone necrosis distal to this point. Function had been suppressed on that side where the ureter was dilated but the kidney unaffected. Obviously she had been living solely on the enlarged right kidney of which the ureter and pelvis were dilated and contained phosphatic aggregations—the source of her skiagraphic opacity—and a little muco-pus. There were merely moderate ileal adhesions to pelvic colon.

Reflection provokes the question, could this patient have been saved by early resort to uretero-colic union?

FIG. 6.—F. P. Post-mortem specimen after uretero-colic union for inveterate leukoplakia of bladder and right ureter.

Tuberculous Cystitis

Specific infection of the bladder may also cause intense incurable suffering and I have been glad to try ureteric transplant to ease the sad lot of two tuberculous cases.

R. W., aged 10 years, is a boy whose painful frequency of many months, with urine repeatedly sterile, I attributed to vesical calculi. His complaint did not abate after litholapaxy and further investigation led me to suspect the right kidney as the "fons et origo" of his trouble. (Pyelography 7.12.43.) Accordingly, on 11.1.44, I explored the loin and removed a tuberculous kidney and ureter. The large kidney was a shell expanded by tuberculous pus and calcareous material, which provided the obvious source of the vesical pathology. Healing was quick and he was discharged to a sanatorium. However, by May 1944, micturition had become so excruciating that his heartrending cries led neighbours to protest. On readmission the house surgeon tried to free debris blocking the urethra, but it was obvious the child was nearing his end so the parents allowed me to turn the flow of urine from the residual left kidney into the colon. Reaction was alarming and, despite intravenous fluids, urine did not appear from the bowel for five days. On 15.6.44, four ounces of pus were drained from the dorsum ili and formal cystostomy done after finding copious foul discharge expressible *per urethram*. Cystitic pain and discharge compelled me to complete the procession of operations by total cystectomy and vesiculo-prostatectomy on 6.7.44. He soon healed, learnt to use his bowel conveniently and became quite a cheery little fellow. A tendency to flat foot has been cured by cycling, but he puts on little weight and now has a blood urea of 95 mg.%. If we cannot hope to give him length of life, at least he is proceeding happily whilst it endures. How much mutilation, suffering and major surgery might have been saved by timely diagnosis!

In the second case, B. L., aged 27, the primary left renal source of her urinary tuberculosis had been removed two and a half years before she reached me in July 1945. She was still disabled and pale with moderate frequency, pain in the right loin and a blood urea of 100 mg.%. Transplant of the right ureter to bowel seemed the only hope for her future. Cystoscopy confirmed the presence of tuberculous ulceration and this was the cause of a dilated right kidney and ureter. Urine from the latter was guinea-pig positive.

These are early days but they are her first delightful ones for a long time and her weight is obviously increasing. "Is there any preferable alternative?" appears a legitimate question.

Vesical Carcinoma

Just as vesical defunctionation has brightened the dark corners of cystitic pathology, so it is offering great promise in the gloomy sphere of bladder cancer. This disease, while unfavourable for conservative surgery, is relatively slow to spread from the bladder. If, therefore, we can treat it radically and dispense with the bladder, the patient's prospects of effective succour are good.

My experience is but recent and starts with a man, F. L., aged 36, sent to me on 30.3.42 with pain and intermittent hæmaturia. Diathermy was tried tentatively but, six months later, a radical operation became imperative and a hydronephrosis had enlarged the right kidney four times. On 2.10.42 I transplanted a normal left ureter to the colon and performed a right cutaneous ureterostomy with corresponding nephrectomy a month later. On palpation of the bladder the growth was felt the size of an orange but movable. Two months after the transplantation, total cysto-prostatectomy was performed, as usual under spinal anaesthesia (fig. 7). Occasional gas and oxygen is added in a few cases. The peritoneal veil remained inviolate. After an eventful convalescence he resumed light work the following summer and, this October (1945), tells me he has only been off work five days in the past two years. Urination is $\frac{D\ 6-8}{N\ 1}$; he

is cheerful, the abdomen feels healthy and he maintains his weight at 11 stone. His blood urea figure is 0.038%, but the pyelogram is of subnormal density and mildly dilated.

G. P., aged 42, came first to me on 29.1.43, having a sixteen months' history of increasing painful frequency and hæmaturia which had already been treated by diathermy and cystostomy. The lesion was obviously advanced carcinoma showing a filling defect with crenated outline in the cystogram and bilateral hydronephrosis. At the transplantation I noted the bladder was the size of a lemon and no extension of the disease beyond it. Swabs of ureteric urines proved to be sterile. The post-operative pyelograms showed full function on the left side and about 50% on the right, which is significant as distension of the right ureter had been noted at the operation. After total cysto-prostatectomy, on 12.5.43, he got on fairly for two or three days but died of obstruction on the fifth day. Post-mortem showed the new urinary drainage system in good working order. There was moderate pelvic peritonitis but the lethal factor was a band acutely obstructing the last two feet of the ileum. A broad adhesion joined the terminal ileum to the pelvic colon. These were due to peritonitis around the previous anastomosis. The newly created effluent system, right ureter included, looks competent in the photo of the specimen and the cadaver appeared clear of neoplastic remains (fig. 8). How poignant are the surgeon's regrets over the fatal adhesions incidental to uretero-colic union, and how pregnant the precautions advocated by Jewett for minimizing such!

H. M., aged 40, started in April 1944 a dull ache in front and back of sacro-iliac region. Frequent painful micturition was gradually added and, by August, blood in the urine which recurred till he came to me in November. He looked in fair health

but obviously distressed. A malignant papilliferous tumour was found on cystoscopy, encircling the bladder neck. The ureters were joined to the colon on 14.11.44, and hiccoughs were notable in an otherwise smooth healing. Six weeks later he had total vesico-vesiculo-prostatectomy and went home well on the eighteenth day. Reviewed on 8.10.45, he looks and feels well. Urination is $\frac{D\ 6-8}{N\ 1-2}$ blood urea was 36 mg.% and post-operative pyelograms show healthy structure. His only complaint is weakness in the back with heavy work.

W. H. J., aged 54, is still more recent, coming in January 1945 with malignant tumour choking the outlet of his bladder which was half-way up to the navel. Hæmaturia troubled him for the previous nine months and marked frequency had supervened. For this man of light build and rather waxy hue the sole effective remedy involved ureteric transplantation which was done on 9.3.45, and he went home in the third week. Bladder washes were done and acute epididymitis allowed to settle, prior to the total cystectomy, 4.5.45. Dr. A. D. Fraser reports: "This is a carcinoma . . . composed of rapid and irregularly growing cells of Malpighian cell layer type . . . marked infiltration of the bladder wall." He is (16.10.45) quite cheerful and wants to start work. He still wears a spare aspect and has recently felt pain in the left groin for which no physical signs are forthcoming apart from a few tender shotty glands. His frequency is $\frac{D\ 3-4\ \text{hourly}}{N\ 3-4\ \text{times}}$ and pyelography shows the left kidney twice its normal size and the right one and a half times.

E. W., aged 69, came in January 1943 the victim of advanced vesical cancer and super-added cystitis. She was the victim, too, of Mars for, having resorted to her doctor two years previously and been labelled cystitis, she was blitzed to a hospital in another town and, when she returned, found her doctor gone to the war! Her incessant vesical spasms were ghastly to behold and I performed ureteric transplantation. She succumbed three days later and autopsy showed a clean peritoneum and clean right ureter but the left was clogged with blood down to a short indwelling tiny rubber tube, the only one used in this series. Kidneys and bladder were grossly septic. Four cancerous foci were seen on base, back and dome of bladder but no extra-vesical deposit.

My last case, Q. P., aged 35—almost equally harrowing a sight and destitute of hope—started her illness in May 1944 with soreness just within the vagina which became severe by September. By January 1945 suprapubic cystostomy was done owing to super-added dysuria and radium used shortly after for urethral cancer. The urogram, when she came to me in August, was informative, revealing good renal excretion. A large hard mass of growth behind the pubes was felt ineradicable, but diversion of urine to the colon offered a faint hope of alleviating her ghastly lot. She died twelve days after the operation and, probably, of terminal collapse of lower lobes of her lungs. The transplants had taken satisfactorily but pyonephrosis and several tiny abscesses had affected the right kidney and in the left was recent mild pyelonephritis. The primary involved the urethra and bladder base and was fused to the symphysis pubis and associated with a few hepatic nodules suggestive of secondary spread. Presumably it started in the urethra.

While the operation earlier might have paved the way to surgical cure of the cancers it was only used as a desperate last resort in these two women. It failed, but nevertheless I believe it worthy of trial as a palliative in some cases of this most distressing form of cancer.

Disease	Total	Op. mort.
Obstetric fistula	1	—
Refract. ulc. cystitis: M.3*, F.4	7	1
Tuberculous cystitis: M.1†, F.1	2	—
Carcinoma vesicæ: M.4, F.2	6	2
	16 (11 bilateral)	3 (2 bilateral)

*Precise pathology uncertain.

†Boy of 10 years—all others adults.

The three fatal cases were so ill prior to operation as to need no further comment. Apart from the obstetric category, the material handled obviously involves a high operative risk so that the results are far from discouraging.

Two cases have died subsequently. One (F. W.), with pyelonephritis, had been a very sickly female for years and the operation played but a small part in her ending. The other (G. P.), with acute obstruction, ranks as a serious surgical disaster pointing to the dangerous complication of adhesive peritonitis.

The Latent Morbidity

What moves me more than the mortality is the *insidious morbidity*, masked clinically by the patients dominating sense of well-being, that often follows this operation. Most cases show dilated urograms and one patient a stone in the kidney. Their weight is apt to be stationary and the blood urea raised. In fact, these features point to early renal impairment; and it is this, rather than infection, that seems to me still to leave the future of these patients somewhat clouded. Is not inflammatory reaction in the colonic bed of the ureter, resulting in fibroses, the pathological crux of the undertaking? To minimize this peri-ureteritis and urinary stasis, the procedure demands most meticulous surgical

performance and, in the seriously-ill types, I hope to try the extra insurance afforded by the two-stage principle introduced by Ferguson and admirably developed by Jewett with his highly specialized technique.

CONCLUSION

From the foregoing it is clear that the operation has established a permanent and important niche in the surgery of many serious vesical disorders. In a minority, it is well that a few weeks should elapse between the transfer of right and left ureters. In a still smaller group, the diversion of one ureter alone may be curative—the patient may have but one. But, whether in certain cases the retro-peritoneal junction represents a real advance, time must decide.

I herewith acknowledge my great collective debt to authors and publishers for their permission to borrow both text and illustrations, and to workers whose names do not appear in the bibliography.

True Aneurysm of Left Renal Artery.—A. J. HERIOT, F.R.C.S.

Mrs. S., aged 49. First seen on 4.12.44. Her complaints were of a swelling in the left side of the abdomen, first noticed five months previously and which had increased in size and, further, there was now a throbbing sensation. She was known to have suffered from high blood-pressure for the previous three years.

Past history.—Nothing significant. Has two children, aged 21 and 22. No history of injury.

Clinical examination revealed that there were two parts to the swelling in the left abdomen—one in the loin, which was definitely renal, without pulsation or bruit—whilst internal to that there was a pulsating tumour, almost certainly aneurysmal. The appearance of the pyelography and retrograde films suggested that this tumour arose from the renal artery rather than from the aorta or splenic vessel.

The following tests were carried out:

Urea concentration test:	Time	Volume	Urea%
	1st hour	40 c.c.	2.3
	2nd hour	62 c.c.	2.65
	3rd hour	37 c.c.	2.4

Blood urea 37 mg. %

Wassermann reaction negative.

Urine: An occasional red blood corpuscle and granular cast seen—otherwise normal.

The blood pressure on admission was 235/145 but with rest in bed prior to operation, the lowest figure was 175/95.

It was felt justifiable to explore this tumour and this was carried out on 15.12.44 by an anterior approach, employing a T incision. Operation confirmed a large aneurysm of the renal artery which, with some difficulty, was freed from the aorta and a short pedicle ligated. Specimen showed a very large aneurysm of the renal artery compressing and deforming the pelvis and histological examination revealed an extreme degree of renal ischaemia. The report on the specimen was as follows: "Compression of the kidney has led to destruction of the normal histological appearances with extensive tubular atrophy. Marked pathological changes are present in the glomeruli and their afferent arterioles. All degrees of hyaline change can be seen in the former, from peri-glomerular fibrosis and early hyalinization with shrinkage of the tuft to, in the majority of cases, complete obliteration

of the glomerulus. No normal glomeruli were seen. Similar severe hyaline changes were seen in the arterioles, which in many cases were completely obstructed. Collections of lymphocytes and a collection of acute inflammatory cells, polymorphs and eosinophils, were present in the kidney and perirenal tissue, and there was also a diffuse scanty infiltration of polymorphs. There was evidence of recent hæmorrhage, probably operative in origin. The general histological picture suggests that an extreme degree of renal ischæmia was present. The wall of the aneurysm consists of rather œdematous fibrous tissue, some of which shows hyaline changes. No endothelial lining was seen. Collections of lymphocytes were present in the wall, many of them containing reticulum cells and having the appearance of true germinal follicles. In some cases these lymphocytic collections were situated in the neighbourhood of the vessels. There was also a little patchy plasma cell infiltration.

Following operation her blood-pressure fell to 130/80 but on final discharge on 27.2.45 it had reached 165/105, whilst examination on 24.11.45 showed a reading of 205/120.

Commentary.—The interesting features of this case are the extreme rarity of renal aneurysms, especially of such a large size, and in this case there is no apparent ætiological factor, although in most previous cases, trauma would appear to be the cause. This kidney, too, exhibits the phenomenon of a Goldblatt kidney, but, despite nephrectomy, after a year the blood-pressure has risen to almost its previous height although the initial fall had been encouraging.

I am very grateful to Mr. J. B. Hunter for permission to treat this case and to Mr. Yates Bell for his help and advice.

Double Urethra in a Male.—J. D. FERCUSSON, F.R.C.S.

True duplication of the male urethra, whether in conjunction with a single or double penis, is a rare anomaly. Slightly less uncommon are those accessory channels which, by reason of their length, are clearly distinguishable from the small blind pits encountered on the glans penis, and around which controversy has raged as to whether they should be regarded as urethral homologues. The case here described belongs to the latter type and exhibits features of interest with regard to its morphology.

FIG. 1.

FIG. 2.

FIG. 3.

L. B., a male patient aged 32, was admitted to the Central Middlesex County Hospital on account of a right-sided epididymo-orchitis of a non-specific nature. On routine examination he was found to possess, in addition to a normally placed urethral orifice, a second smaller aperture opening on the dorsum of the glans (fig. 1). Although no discharge was evident from the normal urethra, the abnormal dorsal orifice emitted a thin white sticky fluid. No specific organisms were detected in this discharge, which had been present for a few days, and there was no history of venereal infection. He stated that he micturated solely through the normally placed aperture, but, that when ejaculation of semen occurred (also from this opening) there was a thin watery discharge from the abnormal channel.

Following the subsidence of the epididymo-orchitis and diminution of the discharge, it was found possible to pass a probe through the small dorsal opening into a sub-cutaneous channel running for a distance of 14 cm. in the dorsal mid-line of the penis. This channel passed beneath the symphysis pubis and seemed to terminate in the prostatic region. Injection of radio-opaque fluid through a ureteric catheter passed into the channel, showed a serpentine continuation at this point, suggestive of a connexion with the right seminal vesicle. Simultaneous urethrocystography was performed through the normally placed urethra, and the combined appearance is shown in the accompanying photograph and diagram (figs. 2 and 3).

From these it will be seen that the normal urethra communicates with the bladder in the usual manner, while the abnormal channel is apparently quite distinct and ends as described above.

The main points of interest in this case appear to be:

(1) The co-existence of right epididymo-orchitis and a discharge only from the dorsally placed aperture, examined in the light of the urethrographic findings.

(2) The anatomical relationship between such dorsally placed channels and the position of the urethra in cases of penile epispadias with sphincteric control.

Owing to the possibility of predisposing the left side of the genital tract to infection, posterior urethroscopy, with a view to establishing the position of the ejaculatory ducts by catheterization, has not been proceeded with.

A somewhat similar case, in which an abnormal dorsal channel communicated, by divarication around the prostate, with both seminal vesicles is recorded by Cruveilhier (1852). A detailed account of further accessory channels is given by Lebrun (1912), and Mackenzie (1916). It is of interest to note that such duplicated "urethras" frequently emit a discharge, the persistence of which may, in some cases, call for extirpation of the track.

Spinal Anæsthesia and its Effect on a Case of Hydronephrosis and Hydro-ureter.—

Squadron Leader HUGO GRANT, R.A.F.

The treatment of achalasia of the intestine by spinal anæsthesia was first shown to be a possibility by Stabins, Morton and Scott when they found that certain cases of megacolon, in which spinal anæsthesia had been used to gauge the effect of a proposed subsequent sympathectomy, were so much improved following the spinal anæsthesia that the sympathectomy was not required. Telford and Simmons reported 7 cases treated and also 1 case of achalasia of the œsophagus also treated with excellent results. A further case of achalasia of the colon was also reported by Court and Hasler.

Ogier Ward treated a case of bilateral hydro-ureter by pre-sacral neurectomy with excellent results—the contraction persisted eleven months later.

The autonomic nerve supply to the urinary tract is as follows:—

The sympathetic innervation is from the renal, testicular and hypogastric plexuses, and supplies the whole of the urinary tract from kidney to the bladder.

The para-sympathetic through the vagus supplies the kidney parenchyma, and through the sacral para-sympathetic supplies the bladder.

As far as is known there is no para-sympathetic supply to the pelvis or ureter.

An analogy between achalasia of the urinary tract and achalasia of the intestine may be observed in that the obstruction of megacolon is said to be related to the fact that this disorder occurs where the sacral para-sympathetic takes over from the vagus.

of the glomerulus. No normal glomeruli were seen. Similar severe hyaline changes were seen in the arterioles, which in many cases were completely obstructed. Spinal Anæsthesia and its Effect on a Case of Hydronephrosis and Hydro-ureter.—

Squadron Leader HUGO GRANT, R.A.F.

The treatment of achalasia of the intestine by spinal anæsthesia was first shown to be a possibility by Stabins, Morton and Scott when they found that certain cases of megacolon, in which spinal anæsthesia had been used to gauge the effect of a proposed subsequent sympathectomy, were so much improved following the spinal anæsthesia that the sympathectomy was not required. Telford and Simmons reported 7 cases treated and also 1 case of achalasia of the œsophagus also treated with excellent results. A further case of achalasia of the colon was also reported by Court and Hasler.

Ogier Ward treated a case of bilateral hydro-ureter by pre-sacral neurectomy with excellent results—the contraction persisted eleven months later.

The autonomic nerve supply to the urinary tract is as follows:—

The sympathetic innervation is from the renal, testicular and hypogastric plexuses, and supplies the whole of the urinary tract from kidney to the bladder.

The para-sympathetic through the vagus supplies the kidney parenchyma, and through the sacral para-sympathetic supplies the bladder.

As far as is known there is no para-sympathetic supply to the pelvis or ureter.

An analogy between achalasia of the urinary tract and achalasia of the intestine may be observed in that the obstruction of megacolon is said to be related to the fact that this disorder occurs where the sacral para-sympathetic takes over from the vagus.

When I came across a case of what was considered at first to be achalasia of the renal tract I determined to try the effect of spinal anaesthesia. As will be seen, however, this was almost certainly not a true case of achalasia but the effects were so striking that I feel that it is worthy of record. In this case the spinal anaesthesia was brought up to the level of at least the seventh thoracic nerve and perhaps a little higher, and it was considered likely that most of the sympathetic innervation had been blocked.

T. H., male, aged 33. This man was admitted with a history of three years' painless haematuria. The only relevant thing to note in his past history was gonorrhoea in 1924 from which he had no trouble subsequently. His blood-pressure was 130/80, his blood W.R. was negative and otherwise general examination revealed no abnormality.

An excretory urogram was taken and this showed on the right side a large hydronephrosis with gross dilatation of the calices and pelvis and gross dilatation also of the whole length of the ureter, with a fair-sized oval calculus at the lower end. There was early excretion of the opaque media. On the left side there was also a slight dilatation of the neck of the lowest calix. The appearance suggested achalasia with secondary calculus formation on the right side. On 1.2.43 a spinal anaesthetic was given, 180 mg. of planocaine was used and after twenty minutes there was complete anaesthesia to almost 1 in. below xiphoid and about 4 in. above umbilicus and above that sensation was modified for a further inch. Another excretory urogram was then taken and on the right side the dilatation had disappeared and the kidney and ureter appeared normal except for the calculus. The left ureter was also diminished in size. This excretory urogram was repeated five weeks later and the dilatation was still largely absent. Unfortunately in the interim a cystoscopy had shown the presence of a diffuse papilloma of a malignant type which involved the trigone of the bladder and obscured both ureteric orifices. A cystotomy was later performed and papillomatous formation was found round both ureteric orifices and involving the trigone of the bladder. The right ureteric orifice was partly closed by adhesions. Section of the papilloma showed a malignant change.

Several cases of idiopathic hydronephrosis where the apparent obstruction was at the pelvi-ureteric junction did not respond to spinal anaesthetic.

Comment.—While this is in some respects a record of mis-diagnosis, it has, I think, shown one important thing, and that is that persistent changes may be produced in cases of disordered anatomy of the urinary tract by temporarily interrupting the sympathetic supply, similar to the changes produced by spinal anaesthesia in megacolon.

Treatment of Slipped Upper Femoral Epiphysis

PRESIDENT'S ADDRESS

By W. B. FOLEY, F.R.C.S.

This is a subject upon which, with one exception, I have nothing new to say on the question of ætiology. It is quite certain, I think, that some factor causes weakening of the epiphysal junction. The slip may then be initiated by slight trauma or even by muscle action only and, once begun, is increased by weight-bearing and the fact that many of these patients are overweight. Trauma can never displace the normal upper femoral epiphysis. If it is severe enough it will fracture the neck of the femur leaving the epiphysis undisturbed, and this was demonstrated experimentally by Ollerenshaw and Wood-Jones (1938). The weakening factor is probably a metabolic one since about 70% of these children are either exceptionally tall or overweight and at least 50% show definite evidence of endocrine (probably pituitary) deficiency. The fact that the condition is frequently bilateral and that other epiphyses are occasionally affected, favours an endocrine cause, but there are still the 30% of apparently normal patients with slipped epiphyses to be accounted for.

The exception I mention is a suggestion which comes from Dr. M. Beckett Howorth of New York (1941) in an article reviewing the results of treatment of 62 cases of slipped epiphysis, adding these to a previous review of 70 cases published in collaboration with Dr. A. B. Ferguson (1931). Dr. Howorth has made a detailed analysis of this large number of cases and I shall have occasion to refer to some of his results later. He thinks that the primary condition is a synovitis of the hip occurring during the period of rapid growth, that is between the ages of 9 and 18, and that this lesion causes circulatory changes in and near the epiphysal disc resulting in decalcification and softening. The actual slipping is merely the natural result of weight-bearing or of slight injury to the softened epiphysal junction. He bases this theory on the observations that the early symptoms and signs are those of synovitis and that the capsule can be seen to be swollen in radiographs and in cases where it is opened at operation. The blood sedimentation rate is usually elevated and early radiographs show very constantly juxta-epiphysal decalcification. Gross and microscopic examination of the synovial membrane shows a simple synovitis and cultures have been consistently negative. Howorth thinks the whole picture suggests infection, and explains the negative cultures by technical inability to isolate the organism or virus concerned or to failure to take the culture early enough.

When I came across a case of what was considered at first to be achalasia of the renal tract I determined to try the effect of spinal anaesthesia. As will be seen, however, this was almost certainly not a true case of achalasia but the effects were so striking that I feel that it is worthy of record. In this case the spinal anaesthesia was brought up to the level of at least the seventh thoracic nerve and perhaps a little higher, and it was considered likely that most of the sympathetic innervation had been blocked.

T. H., male, aged 33. This man was admitted with a history of three years' painless haematuria. The only relevant thing to note in his past history was gonorrhoea in 1924 from which he had no trouble subsequently. His blood-pressure was 130/80, his blood W.R. was negative and otherwise general examination revealed no abnormality.

An excretory urogram was taken and this showed on the right side a large hydronephrosis with gross dilatation of the calices and pelvis and gross dilatation also of the whole length of the ureter, with a fair-sized oval calculus at the lower end. There was early excretion of the opaque media. On the left side there was also a slight dilatation of the neck of the lowest calix. The appearance suggested achalasia with secondary calculus formation on the right side. On 1.2.43 a spinal anaesthetic was given, 180 mg. of planocaine was used and after twenty minutes there was complete anaesthesia to almost 1 in. below xiphoid and about 4 in. above umbilicus and above that sensation was modified for a further inch. Another excretory urogram was then taken and on the right side the dilatation had disappeared and the kidney and ureter appeared normal except for the calculus. The left ureter was also diminished in size. This excretory urogram was repeated five weeks later and the dilatation was still largely absent. Unfortunately in the interim a cystoscopy had shown the presence of a diffuse papilloma of a malignant type which involved the trigone of the bladder and obscured both ureteric orifices. A cystotomy was later performed and papillomatous formation was found round both ureteric orifices and involving the trigone of the bladder. The right ureteric orifice was partly closed by adhesions. Section of the papilloma showed a malignant change.

Several cases of idiopathic hydronephrosis where the apparent obstruction was at the pelvi-ureteric junction did not respond to spinal anaesthetic.

Comment.—While this is in some respects a record of mis-diagnosis, it has, I think, shown one important thing, and that is that persistent changes may be produced in cases of disordered anatomy of the urinary tract by temporarily interrupting the sympathetic supply, similar to the changes produced by spinal anaesthesia in megacolon.

rotation. The tube is placed centrally above the pelvis. This results in an excellent and strictly comparable lateral view of each hip-joint.

The importance of always having radiographs taken of both hips, even though the symptoms are unilateral, lies not only in getting a normal hip for comparison but in the chance of detecting the presence of an unsuspected early slip on the other side, since the condition is often bilateral. The early slight displacement is nearly always backwards rather than downwards, and so may be undetectable in the A.P. view but quite obvious in the lateral. In the A.P. view, however, there is very constantly seen a well-marked zone of decalcification in the juxta-epiphyseal portion of the metaphysis.

Treatment.—In 1938 Dr. Philip Wilson of New York published a report of 9 cases of early slipping of the upper femoral epiphysis treated by the insertion of a Smith-Petersen tri-flanged pin across the epiphyseal line into the epiphysis, without any preliminary manipulation or attempt at correction of deformity. His criterion of the degree of displacement which could be safely accepted as compatible with normal subsequent function, except for a possible slight limitation of internal rotation, was that clinically there should be free abduction and not more than 10 degrees of fixed external rotation, that the A.P. radiograph should show the upper border of the epiphysis well above the surface of the neck, and that, in the lateral view, the epiphysis should not be displaced posteriorly more than one-third of the diameter of the neck.

After pinning, these patients were kept in bed without splintage or restraint for an average of two weeks and then allowed up on crutches with some raising of the shoe on the sound side. Weight-bearing was allowed in about two months' time. The Smith-Petersen pin was removed at the end of nine to twelve months after insertion, at which time there was radiographic evidence of fusion of the epiphysis in all cases.

The functional results were excellent in every case, the only abnormality being a varying degree of restriction of internal rotation of the affected hip. The maximum shortening was 1 in. in one case in which there was no shortening before operation. There was $\frac{1}{2}$ in. shortening in one other case which had no pre-operative shortening. This absence of material shortening in spite of the early fusion of the epiphysis requires some explanation. The age of closure of this epiphysis has usually been given in the standard textbooks of anatomy as 18 years but Wilson quotes the researches of Cohn (1924), based on radiographic studies, in fixing it at 15 years. Only 17% of the total growth in length of the lower limbs normally takes place at the upper femoral epiphysis, and Wilson suggests that most of this takes place early, and that there is probably very little growth after the age of 12 years till final closure at 15 years. He has also observed that there is usually premature closing of the epiphysis on the opposite side even if there has been no evidence of slipping. These two reasons would account for the absence of any marked inequality in growth in the children aged 12 and over who form the majority of the cases. One might anticipate rather more shortening in the relatively small age-group under 12.

Wilson states that he has made a thorough trial of weight-bearing calipers and ambulatory plasters and rejected them as inefficient and dangerous, since he has seen complete displacement of the epiphysis occur in patients who were being treated by these methods. There are obvious objections to long-continued traction or plaster immobilization in recumbency, if they can be avoided. At the same time it should be understood that these older methods can produce a perfectly good functional result, only they will have to be continued till there is radiographic evidence of fusion of the epiphysis, which may take as long as twelve months. During this period the patient is subjected to more discomfort and interference with normal activity, and is less efficiently protected against further slipping, than when pin fixation is used.

Howarth reports results classified as excellent or good in 39 out of 40 early cases, but used bone slivers passed through drill holes from the neck across the epiphyseal line. He did not use the Smith-Petersen pin because he did not think it hastened fusion of the epiphysis, but that this is not correct is shown by Wilson's cases and my own in all of which there was radiographic evidence of fusion in six months or less. The pin is simpler to use than bone grafts, gives greater security of fixation, and does not require arthrotomy of the hip.

I have only been fortunate enough to get five cases in which the diagnosis was made early enough to conform to Wilson's standard. All these cases were pinned without previous manipulation or traction. The technique is exactly the same as for pinning the fractured femoral neck and presents no special difficulty to anyone with experience

I can confirm these observations from my own cases, i.e. the swelling of the synovial membrane seen at operation, the histological finding of a simple synovitis, the elevation of the blood sedimentation rate in early cases and the constant appearance of justa-epiphysal decalcification in radiographs. We are all familiar with cases of transient synovitis of the hip in much younger children and Howorth's suggestion is an interesting one and would account for the cases with no sign of endocrine disturbance. I should, however, expect an infective synovitis of the hip to produce more muscle spasm than is usually present in early cases of slipped epiphysis, and the decalcification to be more general. Also if an inflammatory ætiology is to be accepted to the exclusion of an endocrine one it is perhaps a less likely though not impossible explanation of the bilateral cases. Except perhaps for the raised sedimentation rate and Howorth's statement that he has observed these changes in hips operated on before there was any demonstrable epiphysal slipping, these findings might be due to traumatic synovitis and secondary to the epiphysal slipping rather than the primary cause of it.

Osteo-arthritis in later life.—It is a matter of common knowledge that osteo-arthritis of the affected hip-joint is an all too frequent sequel of uncorrected or partially corrected epiphysal displacement though it may not manifest itself for several decades. If it be conceded that this type of arthritis is due chiefly, if not entirely, to mechanical irritation caused by the misfit of the deformed femoral head and neck it is obvious that prevention or correction of such deformity as completely as possible should be regarded as a primary object of treatment in the early stages.

The cases can be sharply divided into two main groups, between which is a great gulf fixed, since treatment in the one is so much more satisfactory than in the other: I. Early cases with minimal epiphysal displacement. II. Cases with severe or complete displacement of the epiphysis.

The latter may be further subdivided into (a) acute cases with a short history usually including slight injury and symptoms and signs severe enough to suggest a fracture of the neck of the femur, and (b) those with a long quiet history of gradually increasing pain and deformity.

Group I. Early cases with minimal epiphysal displacement.—This is the most important group because it is the only one in which treatment can be said to be completely satisfactory. Since inclusion in it depends on one thing only—early diagnosis—I should like at this point to stress the paramount importance of diagnosing cases of slipped femoral epiphysis at the earliest possible moment. Those of us who are concerned with the teaching of students or with the post-graduate instruction of general practitioners should take every opportunity of impressing upon them the extreme importance of suspecting this condition in any adolescent of either sex, between the ages of 9 and 18, who is complaining of limping or of pain in the hip or knee. Much emphasis should also be laid on the urgency of admitting these cases to hospital forthwith, or, if this is impossible, of confining them strictly to bed at home pending admission. Once the diagnosis is made, or even suspected but not confirmed by radiograph, all weight-bearing should be forbidden absolutely, since, if continued, there is a grave risk that at any moment the case may pass from the favourable first group to the less favourable second group.

Diagnosis.—Diagnosis in the really early case which is so favourable for treatment may not be at all obvious clinically. Suspicion should be aroused by a history of intermittent limp in an adolescent especially if accompanied by transient pain in hip or knee. Not infrequently pain in the knee is the only complaint but, if unaccompanied by physical signs in that joint, it should be realized that this is referred pain and attention concentrated upon the hip. Muscle spasm may be absent, but there is usually some limitation of internal rotation of the hip and occasionally of abduction and flexion with pain and spasm at the limits of these movements. There will be no pyrexia but the blood sedimentation rate, if estimated, will usually be moderately raised. Diagnosis rests finally on the radiographs and the technique of taking these is most important. Both hips should always be radiographed in such a way that they are shown in exactly comparable positions in both A.P. and lateral views on the same film. This is straightforward as regards the A.P. view, the patient lying with the lower limbs extended at hip and knee, parallel to each other and with the patellæ pointing straight upward unless there is fixed external rotation of the affected hip. The lateral view is obtained by flexing both hips and knees to exactly the same angle and allowing the hips to fall outwards into as much abduction as they will comfortably take and some external

a diagnosis. Subsequently one of two things may happen. Either pain and/or deformity gradually increase until the patient is forced to seek advice and the diagnosis is obvious, or, usually as the result of trauma, pain becomes suddenly very severe, deformity, especially external rotation, marked and the patient is completely disabled and presents the clinical picture of a fracture of the neck of the femur. Radiographs in either group confirm the diagnosis of severe downward and backward displacement of the upper femoral epiphysis. I should like to discuss the treatment of what may be termed the acute case first.

Such cases should be regarded as urgent emergencies and admitted to hospital forthwith, since every hour of delay makes a successful result less probable. The object of treatment is to replace the slipped epiphysis as completely as possible, and if this is successful to fix it with a Smith-Petersen pin. Two closed methods are available for the reduction of the deformity: (1) gentle manipulation; (2) strong continued traction on the limb. Neither of these methods, especially traction, is likely to succeed unless applied within a week, though there are frequent exceptions to this.

Manipulative reduction.—If manipulation is to be followed by immediate pinning, as it should be if successful, the patient is prepared for operation and placed on an orthopædic table with the usual radiographic set-up of 2 portable tubes in position for taking A.P. and lateral radiographs. I usually adopt the Leadbetter (1933) type of manipulation, which gives good results in reducing fractures of the neck of the femur, and, if the slip has been a recent one, reduction often takes place surprisingly easily and completely with slight crepitus. The reduction is checked radiographically and, if sufficiently good, the limb is fixed in abduction and internal rotation and pinning carried out.

If manipulation fails it is useless and harmful to make repeated attempts and no force must be used. Advantage may be taken of the anæsthetic and the prepared state of the patient to insert a Steinmann pin through the lower third of the femur in preparation for the alternative method of strong continued traction.

In both these groups and in those next to be mentioned involving arthrotomy of the hip-joint the after-care is somewhat different to the routine already described for the early cases. The patients are kept longer in bed, usually at least a month, often with a light weight and pulley traction for the first two weeks or so. Walking on crutches without weight-bearing is continued for at least three months and sometimes for as long as six months, depending on the radiographic appearances.

Howorth reported only three partial successes out of 21 cases of manipulative reduction. These cases, however, were not pinned but immobilized in plaster following reduction, and most of them had some permanent limitation of movement. He felt that better results would have been obtained by resting these patients in bed till the condition was quiescent, and then doing sub-trochanteric osteotomy. He advised manipulation in very recent cases only and thought immediate pinning would be preferable to plaster fixation.

In classifying my own cases throughout I use the term "excellent" for patients who are quite symptom free and have either no limitation of hip movement or a few degrees of limitation of internal rotation only. Radiography shows no deformity or evidence of arthritis. Cases marked "good" are leading lives of normal activity with no pain, or only an occasional ache with weather changes, but have definite limitation of internal rotation and possibly also of flexion and abduction. Radiography may show some deformity of head or neck, but no arthritic changes. Results classified as "bad" have pain and/or gross limitation of all hip movement and possibly some fixed deformity. Radiography shows evidence of avascular necrosis or of arthritis.

Eight cases have been treated by manipulative reduction. Three of them were subsequently immobilized in plaster, and in the other five the reduced epiphysis was pinned. In the former group the follow-up period ranges from eight to fourteen years with an average of ten years. Results: Excellent 1; bad 2. One of these subsequently needed arthroplasty of the hip.

The follow-up period of the pinned cases extends from one to seven years averaging five years. Results: Excellent 2; good 2; bad 1.

Total cases 8. Excellent 3; good 2; bad 3 (37%).

The one bad result out of the five pinned cases was the most recent.

of the latter and working with proper facilities especially as regards the necessary radiographic checking during the operation. The after-care consisted of two weeks free in bed, followed by discharge from hospital and two months on crutches with an inch of raising of the shoe on the unaffected side. After this full weight-bearing activity was allowed and the pins were removed at the end of a year or so at which time the epiphysis was fused in every case.

The follow-up period has ranged from one year to seven years with an average of four years. The results have been excellent in every case and compatible with full normal activity. There was $\frac{1}{4}$ in. shortening in one case only and slight limitation of internal rotation in 3 cases.

I am definitely in agreement with Wilson that, given good facilities and a surgeon of some experience in the technique of pinning, this is the method of choice in treating the early case of slipped epiphysis. Under those conditions it is safe, certain and associated with a minimum of hospitalization, discomfort and inconvenience to the patient. The only theoretical objection, the desirability of a second operation to remove the pin, has not proved to be one in practice. There has been no difficulty in getting consent and a fortnight in hospital is usually all that is needed.

CASE I.—M. W. This patient, then aged 14, was first seen in May 1938 and gave a definite history of pain in the left thigh and limp for seven weeks. An occasional transitory limp had been noticed over a longer period. On examination there was

FIG. 1.—Lateral view. Slip does not exceed one-third diameter of neck.

FIG. 2.—After pinning.

FIG. 3.—End-result. Note epiphyseal fusion.

CASE I. (M. W.)

slight limitation of abduction and definite limitation of internal rotation of the left hip. Radiographs showed little deformity in the A.P. view but a characteristic juxta-epiphyseal decalcification, and the lateral view showed the epiphysis displaced posteriorly but not more than one-third the diameter of the neck. It was decided to accept this position and the epiphysis was pinned without any attempt at correction. The patient was discharged from hospital on crutches on the sixteenth post-operative day and the crutches were discarded and weight-bearing allowed two months later. She now works at a job which involves standing all day and engages in every form of athletic activity she wishes without any discomfort. She has a full range of movement of the affected hip in every direction, and $\frac{1}{4}$ in. shortening only.

GROUP II. *Cases with severe or complete displacement of the epiphysis.*—In these cases there is usually, on close questioning, a fairly long history of occasional limping and pain in hip or knee sometimes not severe enough to make the patient consult a doctor at all or, if a doctor is seen, there is insufficiently thorough investigation to make

a diagnosis. Subsequently one of two things may happen. Either pain and/or deformity gradually increase until the patient is forced to seek advice and the diagnosis is obvious, or, usually as the result of trauma, pain becomes suddenly very severe, deformity, especially external rotation, marked and the patient is completely disabled and presents the clinical picture of a fracture of the neck of the femur. Radiographs in either group confirm the diagnosis of severe downward and backward displacement of the upper femoral epiphysis. I should like to discuss the treatment of what may be termed the acute case first.

Such cases should be regarded as urgent emergencies and admitted to hospital forthwith, since every hour of delay makes a successful result less probable. The object of treatment is to replace the slipped epiphysis as completely as possible, and if this is successful to fix it with a Smith-Petersen pin. Two closed methods are available for the reduction of the deformity: (1) gentle manipulation; (2) strong continued traction on the limb. Neither of these methods, especially traction, is likely to succeed unless applied within a week, though there are frequent exceptions to this.

Manipulative reduction.—If manipulation is to be followed by immediate pinning, as it should be if successful, the patient is prepared for operation and placed on an orthopaedic table with the usual radiographic set-up of 2 portable tubes in position for taking A.P. and lateral radiographs. I usually adopt the Leadbetter (1933) type of manipulation, which gives good results in reducing fractures of the neck of the femur, and, if the slip has been a recent one, reduction often takes place surprisingly easily and completely with slight crepitus. The reduction is checked radiographically and, if sufficiently good, the limb is fixed in abduction and internal rotation and pinning carried out.

If manipulation fails it is useless and harmful to make repeated attempts and no force must be used. Advantage may be taken of the anesthetic and the prepared state of the patient to insert a Steinmann pin through the lower third of the femur in preparation for the alternative method of strong continued traction.

In both these groups and in those next to be mentioned involving arthrotomy of the hip-joint the after-care is somewhat different to the routine already described for the early cases. The patients are kept longer in bed, usually at least a month, often with a light weight and pulley traction for the first two weeks or so. Walking on crutches without weight-bearing is continued for at least three months and sometimes for as long as six months, depending on the radiographic appearances.

Howorth reported only three partial successes out of 21 cases of manipulative reduction. These cases, however, were not pinned but immobilized in plaster following reduction, and most of them had some permanent limitation of movement. He felt that better results would have been obtained by resting these patients in bed till the condition was quiescent, and then doing sub-trochanteric osteotomy. He advised manipulation in very recent cases only and thought immediate pinning would be preferable to plaster fixation.

In classifying my own cases throughout I use the term "excellent" for patients who are quite symptom free and have either no limitation of hip movement or a few degrees of limitation of internal rotation only. Radiography shows no deformity or evidence of arthritis. Cases marked "good" are leading lives of normal activity with no pain, or only an occasional ache with weather changes, but have definite limitation of internal rotation and possibly also of flexion and abduction. Radiography may show some deformity of head or neck, but no arthritic changes. Results classified as "bad" have pain and/or gross limitation of all hip movement and possibly some fixed deformity. Radiography shows evidence of avascular necrosis or of arthritis.

Eight cases have been treated by manipulative reduction. Three of them were subsequently immobilized in plaster, and in the other five the reduced epiphysis was pinned. In the former group the follow-up period ranges from eight to fourteen years with an average of ten years. Results: Excellent 1; bad 2. One of these subsequently needed arthroplasty of the hip.

The follow-up period of the pinned cases extends from one to seven years averaging five years. Results: Excellent 2; good 2; bad 1.

Total cases 8. Excellent 3; good 2; bad 3 (37%).

The one bad result out of the five pinned cases was the most recent.

CASE II.—J. W. This child, aged 11, was seen in July 1944 with a typical history of three months' occasional pain and limp and one week's severe pain and inability to walk following a fall. There was an external rotational deformity of 60 degrees, limitation of movement in every direction by muscle spasm, and the blood sedimentation rate was raised to 14 mm. in the hour. The radiograph shows almost complete downward and backward displacement of the epiphysis. Although nine days had elapsed since the presumed time of slipping, reduction was quite easily accomplished by the Leadbetter method without any force at all, and the check radiograph showed this to be complete in both planes. The reduced epiphysis was pinned, the patient was discharged from hospital three weeks later on crutches, and weight-bearing was not allowed for four and a half months. Now, just over a year since reduction, pain, limp and limitation of movement in every direction have recurred and radiographs show failure of epiphyseal fusion, partial extrusion of the pin and recurrence of deformity, and changes in the femoral head suggestive of early avascular necrosis. This was a disappointing result but shows that there is always a risk of ischaemic changes following closed manipulation at the epiphyseal line.

Watson-Jones (1944) attributes these ischaemic changes to over-stretching of the ligamentum teres, already stretched by the backward displacement, causing damage and thrombosis to its vessels, which may be in these cases the chief blood supply left to the epiphysis.

If this is so, as may well be the case, the fair proportion of good results would be those in which, more by luck than by skill, the ligament escapes damage during manipulation.

As one cannot control this result of manipulation and the percentage of cases ending in avascular necrosis is as high as 25% to 30% the method should, I think, be abandoned.

Avascular necrosis is a complication not to be regarded lightly, since it may lead to fibrous ankylosis of the hip or to much limitation of the range of movement and early onset of arthritis.

FIG. 4.—A.P. view. Severe epiphyseal displacement.

FIG. 5.—A.P. view after reduction by closed manipulation and pinning.

FIG. 6.—Deformity of femoral head and ischaemic changes one year after reduction.

CASE II. (J. W.)

Reduction by strong traction.—Skeletal traction by a Steinmann pin through the lower third of the femur is preferred, and the patient may be placed on a frame or the affected limb suspended in a Thomas' splint. There is nothing to be gained by abducting the limb. Weights up to 20 lb. may be used but this strength of traction should not be maintained longer than fourteen days at the outside, as there is some risk of interference with blood supply from the continuous tension of the capsule. If reduction is going to take place it will usually do so within that period. The tendency in this method is to get correction of the downward but not of the backward displacement owing to failure of the epiphysis to rotate. Should it prove successful enough to give an acceptable position the weights are reduced to 10 lb. or less so as to maintain

correction and the reduced epiphysis fixed by a Smith-Petersen pin at the earliest opportunity. Howorth found that this method corrected downward displacement but not backward rotation in most cases. The majority had radiographic changes in the head subsequently suggestive of avascular necrosis and eventual movement was good in one hip only, fair in one and poor in the others. He thinks these poor results were probably due to injury to the capsule and the circulation by the traction and the tension in plaster. I think this is too gloomy a picture of reduction by traction which is the safest method though not always fully effective unless applied early. Howorth's cases were not pinned and he thinks the results would have been better if immediate pinning had followed reduction. Two of my cases out of a number in which this method was tried got a satisfactory reduction in both planes and were pinned. The result in each case was excellent. The cases in which traction failed to reduce were dealt with by other methods but one case, in which strong traction was continued for too long, got a bad result with much restriction of hip movement and changes in the radiograph typical of avascular necrosis.

The following case was bilateral and illustrates well some of the points I made earlier with regard to diagnosis and the necessity of insisting on immediate cessation of weight-bearing.

CASE III.—M. C. This girl, aged 13, was first seen in another department on 3.11.42 with a history of left-sided limp for about two months and of pain in the left hip for the past three days. Radiographs were ordered but not examined at the time and consisted of an A.P. view of the hips only. The patient was instructed to attend for re-examination in a week's time, but weight-bearing was not forbidden. A week later,

FIG. 7.—Left hip. A.P. view.

FIG. 8.—Left hip. After reduction by strong traction and pinning.

FIG. 9.—Left hip. End-result.

CASE III. (M. C.)

when I was asked to see her, there was a fixed external rotational deformity of the left hip, movement was painful and restricted in every direction by muscle spasm, and subsequent radiographs of both hips in both planes showed not only a nearly complete downward and backward displacement of the left upper femoral epiphysis, but an early backward slip of the right upper femoral epiphysis. There had been no symptoms on the right side and no physical signs on examination. There is no doubt that the major displacement of the left epiphysis took place during the week between the two examinations, and could have been prevented if weight-bearing had been forbidden. The patient was admitted to hospital forthwith and it was decided to accept the position of the right epiphysis and this was pinned without any manipulation. Under the same anaesthetic a Steinmann pin was drilled through the lower third of the left femur and strong weight traction, applied for four days, resulted in a satisfactory reduction. This epiphysis was also subsequently fixed by a Smith-Petersen pin. The patient is now free of all symptoms and has no material limitation of movement of either hip-joint.

CASE II.—J. W. This child, aged 11, was seen in July 1944 with a typical history of three months' occasional pain and limp and one week's severe pain and inability to walk following a fall. There was an external rotational deformity of 60 degrees, limitation of movement in every direction by muscle spasm, and the blood sedimentation rate was raised to 14 mm. in the hour. The radiograph shows almost complete downward and backward displacement of the epiphysis. Although nine days had elapsed since the presumed time of slipping, reduction was quite easily accomplished by the Leadbetter method without any force at all, and the check radiograph showed this to be complete in both planes. The reduced epiphysis was pinned, the patient was discharged from hospital three weeks later on crutches, and weight-bearing was not allowed for four and a half months. Now, just over a year since reduction, pain, limp and limitation of movement in every direction have recurred and radiographs show failure of epiphyseal fusion, partial extrusion of the pin and recurrence of deformity, and changes in the femoral head suggestive of early avascular necrosis. This was a disappointing result but shows that there is always a risk of ischæmic changes following closed manipulation at the epiphyseal line.

Watson-Jones (1944) attributes these ischæmic changes to over-stretching of the ligamentum teres, already stretched by the backward displacement, causing damage and thrombosis to its vessels, which may be in these cases the chief blood supply left to the epiphysis.

If this is so, as may well be the case, the fair proportion of good results would be those in which, more by luck than by skill, the ligament escapes damage during manipulation.

As one cannot control this result of manipulation and the percentage of cases ending in avascular necrosis is as high as 25% to 30% the method should, I think, be abandoned.

Avascular necrosis is a complication not to be regarded lightly, since it may lead to fibrous ankylosis of the hip or to much limitation of the range of movement and early onset of arthritis.

FIG. 4.—A.P. view. Severe epiphyseal displacement.

FIG. 5.—A.P. view after reduction by closed manipulation and pinning.

FIG. 6.—Deformity of femoral head and ischæmic changes one year after reduction.

CASE II. (J. W.)

Reduction by strong traction.—Skeletal traction by a Steinmann pin through the lower third of the femur is preferred, and the patient may be placed on a frame or the affected limb suspended in a Thomas' splint. There is nothing to be gained by abducting the limb. Weights up to 20 lb. may be used but this strength of traction should not be maintained longer than fourteen days at the outside, as there is some risk of interference with blood supply from the continuous tension of the capsule. If reduction is going to take place it will usually do so within that period. The tendency in this method is to get correction of the downward but not of the backward displacement owing to failure of the epiphysis to rotate. Should it prove successful enough to give an acceptable position the weights are reduced to 10 lb. or less so as to maintain

through the epiphysial junction and immediate pinning were carried out on 28.1.44. The patient was kept in bed for three weeks, and weight-bearing on the affected hip was not allowed for six months. The present condition, nearly two years after operation, is excellent, since there is no pain, no material restriction of movement and no shortening. Radiographs show a normal position of the femoral head, fusion of the epiphysial junction and no evidence of ischæmic changes.

CASE V.—I. B. This girl, then aged 13, was admitted to hospital on 9.8.40 with a history of intermittent pain in the left hip and knee for eight months, and a great and sudden increase in pain and disability following a fall two weeks before admission. There was an external rotational deformity of 70 degrees and limitation of movement of the left hip in every direction by muscle spasm. Radiographs showed a nearly complete downward and backward displacement of the left upper femoral epiphysis.

FIG. 13.—A.P. view of epiphysial displacement.

FIG. 14.—A.P. view after open reduction and pinning.

FIG. 15.—Deformity of head and ischæmic changes four years after reduction.

CASE V. (I. B.)

After a short period of rest in bed open reduction through the epiphysial junction followed by pin fixation was carried out on 16.8.40. The patient was allowed up a month later, and walked on crutches without weight-bearing on the affected limb for more than six months. On 2.6.43, three years after the operation, the patient was beginning to complain of pain and radiographs showed loss of joint space, deformity of the head and evidence of avascular necrosis. Pain continued to increase in spite of periods of rest in bed with light traction and removal of the pin and finally arthrodesis of the hip was performed on 9.2.44 and has resulted in satisfactory fusion in good functional position.

The ischæmic changes are probably caused in these cases also by damage to the ligamentum teres due to the leverage on the head during reduction, accentuated by the complete temporary separation at the epiphysial junction and the operative trauma to the capsule.

If reduction by closed manipulation is to be considered unjustifiable, that by open mobilization of the epiphysial junction must be considered even more so, as the results, even with immediate pinning as opposed to plaster fixation, are bad in too high a proportion of cases.

If reduction by strong traction fails and if both closed and open manipulation are to be condemned—as I am afraid they should be—what remains? Light traction may be continued till the epiphysis is fused in the position of deformity and this then corrected by wedge osteotomy of the neck of the femur, or by subtrochanteric osteotomy. The former may be carried out much sooner than the latter since the pin used to fix the fractured neck is made to pass across the epiphysial line into the epiphysis and this prevents further slipping and hastens fusion.

Reduction by open operation.—If strong traction fails to reduce the displacement within fourteen days, this can be effected by open operation.

Open reduction through the epiphysal junction.—This is an attractive operation since it gives almost perfect anatomical correction of the displacement, but it is liable to be followed by ischemic changes in about the same proportion of cases as closed manipulation. It is not a particularly easy operation, is time consuming when followed—as it should be—by pinning with the necessary radiographic checking, and should not be lightly undertaken without first-class facilities. The capsule, exposed by the Smith-Petersen approach, is opened. Only the anterior edge of the epiphysis is visible when the limb is fully externally rotated. A gouge, or in many cases a blunt instrument only, is passed gently between the epiphysis and the neck until the latter moves independently of the former when the limb is rotated. Using the instrument between the bones as a skid and to fix the epiphysis, reduction is effected by an assistant abducting and internally rotating the limb. Reduction is checked by radiographs in 2 planes and, if satisfactory, the capsule and upper aponeurotic portion of the wound are closed and the guide wire and Smith-Petersen pin introduced from the outer aspect of the trochanter in the usual manner.

Howorth reported 17 cases treated by open reduction. 11 of these were immobilized in plaster for ten to twelve weeks after reduction. The follow-up period was two and a half to seven years with an average of five and a half years. There were only 2 good results both of which had a preliminary period of rest in bed with light traction. There were 2 complete failures necessitating arthrodesis in the one case and arthroplasty in the other. The other 6 cases were pinned or screwed after open reduction. Follow-up period averaged two and a half years. 2 were classed as very good, 3 fair and 1 poor. Howorth definitely considered immediate internal fixation with early active movement preferable and advised a preliminary period of rest with light traction in all cases in which muscle spasm was present.

I have treated 9 cases by open reduction through the epiphysal junction. The follow-up period ranged from two years to seven years with an average of three and a half years. Results: Excellent 1; good 5; bad 3 (33%).

The 3 bad results were due to avascular necrosis of the epiphysis resulting in restriction of movement amounting to fibrous ankylosis and in 1 case accompanied by pain of sufficient severity to make arthrodesis necessary.

CASE IV.—C. F. The short term results can be good enough. This patient aged 16 slipped and hurt his right hip fifteen days before admission on 13.1.44. This caused a

FIG. 10.—Lateral view. Complete backward displacement.

FIG. 11.—A.P. view after open reduction and pinning.

FIG. 12.—End-result, two years after reduction.

CASE IV. (C. F.)

limp and a second fall six days later was followed by a marked increase in pain and limping. Radiographs showed a nearly complete slip of the epiphysis especially backwards. Strong traction failed to affect the backward rotation and open reduction

through the epiphysial junction and immediate pinning were carried out on 28.1.44. The patient was kept in bed for three weeks, and weight-bearing on the affected hip was not allowed for six months. The present condition, nearly two years after operation, is excellent, since there is no pain, no material restriction of movement and no shortening. Radiographs show a normal position of the femoral head, fusion of the epiphysial junction and no evidence of ischæmic changes.

CASE V.—I. B. This girl, then aged 13, was admitted to hospital on 9.8.40 with a history of intermittent pain in the left hip and knee for eight months, and a great and sudden increase in pain and disability following a fall two weeks before admission. There was an external rotational deformity of 70 degrees and limitation of movement of the left hip in every direction by muscle spasm. Radiographs showed a nearly complete downward and backward displacement of the left upper femoral epiphysis.

FIG. 13.—A.P. view of epiphysal displacement.

FIG. 14.—A.P. view after open reduction and pinning.

FIG. 15.—Deformity of head and ischæmic changes four years after reduction.

CASE V. (I. B.)

After a short period of rest in bed open reduction through the epiphysial junction followed by pin fixation was carried out on 16.8.40. The patient was allowed up a month later, and walked on crutches without weight-bearing on the affected limb for more than six months. On 2.6.43, three years after the operation, the patient was beginning to complain of pain and radiographs showed loss of joint space, deformity of the head and evidence of avascular necrosis. Pain continued to increase in spite of periods of rest in bed with light traction and removal of the pin and finally arthrodesis of the hip was performed on 9.2.44 and has resulted in satisfactory fusion in good functional position.

The ischæmic changes are probably caused in these cases also by damage to the ligamentum teres due to the leverage on the head during reduction, accentuated by the complete temporary separation at the epiphysial junction and the operative trauma to the capsule.

If reduction by closed manipulation is to be considered unjustifiable, that by open mobilization of the epiphysial junction must be considered even more so, as the results, even with immediate pinning as opposed to plaster fixation, are bad in too high a proportion of cases.

If reduction by strong traction fails and if both closed and open manipulation are to be condemned—as I am afraid they should be—what remains? Light traction may be continued till the epiphysis is fused in the position of deformity and this then corrected by wedge osteotomy of the neck of the femur, or by subtrochanteric osteotomy. The former may be carried out much sooner than the latter since the pin used to fix the fractured neck is made to pass across the epiphysial line into the epiphysis and this prevents further slipping and hastens fusion.

Osteotomy of the neck.—The technique of this method conforms to that just described in all particulars except that no attempt is made to identify and mobilize the epiphysial junction. A wedge of bone with base looking forward or upward according to the predominant deformity, is removed with a fine sharp chisel from the most prominent presenting portion of the neck, the resulting gap closed by abducting and internally rotating the limb, and a Smith-Petersen pin passed across the fracture line and well into the epiphysis. The cut sections of neck are often of slightly different diameter and do not appose perfectly leaving a slight step, but this does not seem to have any material effect on subsequent function and is not apparent in later radiographs.

Of the 9 cases treated in this way 5 were immobilized in plaster following operation, and 4 were pinned. The average follow-up period of the 5 plaster cases was eight years and the results are all classified as good. The follow-up period of the pinned cases is shorter ranging from one to three years, with an average of two years. 1 case is classified as excellent, and the other 3 as good. The majority of these cases have some shortening, but in no case exceeding 1 in. Most of them have some limitation of internal rotation and in some cases of flexion and abduction as well. Restoration of mobility of the affected hip was much speedier and rather more complete in the pinned cases than in those immobilized in plaster after operation.

CASE VI.—D. T. This was one of the cases with a long history (one year) of limp and gradual development of shortening and deformity of the left lower limb. Except

FIG. 16.—Slipped epiphysis and deformity of neck.

FIG. 17.—Radiograph during operation after wedge osteotomy of neck and pinning.

FIG. 18.—End-result three and a half years after operation.

CASE VI. (D. T.)

for some transient pain and stiffness of the left knee after a fall the patient made no complaint of pain whatever. His age was 15 at the time of admission to hospital on 28.4.42. He had then a fixed external rotation deformity of 45 degrees and flexion and abduction were limited but more from mechanical block than from muscle spasm. Radiographs showed slipping of the epiphysis and marked coxa vara deformity of the neck. It seemed obvious that nothing could be accomplished here by manipulation or traction and that a wedge osteotomy of the neck would be a better procedure than any attempt at mobilizing the already probably partly fused epiphysial junction. This was carried out on 1.5.42 and a pin inserted across the fracture line and well into the epiphysis. The patient was discharged from hospital six weeks later on crutches but weight-bearing was not allowed for seven months. The result is classed as good since the patient is doing heavy work as a farm labourer without any complaint of pain or disability whatever, but he has some limitation of flexion, and marked limitation of internal rotation and 1 in. shortening. Radiographs show a shortened, widened neck with approximately normal angle and some deformity of the head, which may lead to trouble in later life, but at present no evidence of avascular necrosis or of arthritis. This is a fairly typical end-result of this procedure. The absence of ischaemic changes following this operation is probably due to the clean division of the neck allowing correction of deformity without exerting any leverage on the head.

The anatomical correction of deformity is fairly good, but by no means perfect, and though the short-term functional results are good, it remains to be seen whether the long-term results are better than those obtained by subtrochanteric osteotomy.

Subtrochanteric osteotomy.—This operation is much simpler than the others and avoids whatever risk may be associated with arthrotomy of the hip-joint. The division of the bone just below the lesser trochanter is best done by the ball and socket type of osteotomy rather than by removing a wedge, since the former method facilitates the correction of external rotation deformity as well as allowing the necessary abduction at the osteotomy level. It is wise to control the mobile upper fragment by the insertion of a Steinmann pin into the greater trochanter before the bone is divided. This pin may be subsequently included in the plaster spica. The abduction at the osteotomy level has the effect of restoring an approximately correct angle of the neck when the limb is in the normal weight-bearing position and the external rotational deformity is corrected.

Investigation of the results of this operation have been disappointing from lack of information. A number of cases operated upon in 1920-30, the earliest of which I have records, are now of military age and an examination call-up or alternative questionnaire has for the most part failed to produce any response. The reasonable assumption that most of these patients are in the Services might in itself indicate that their functional results are at least fairly satisfactory. Of those I have been able to trace the results are rather mixed. One man fifteen years after operation was working as a gardener and had not been off work because of his hip for ten years, but he complained of some aching in the hip and knee and radiographs showed osteo-arthritic changes. Another man fourteen years after operation was standing long hours in a bakery and only complained of slight pain at changes of weather: radiographs showed deformity but no evidence of arthritis.

In contrast to this good result a third patient three years only after operation had a decreasing range of movement in every direction and evidence of gross arthritic changes in the radiographs. He was not so far complaining of pain. Two other patients eight years from operation both complained of some pain on walking and stiffness after sitting. Radiographs showed deformity but no definite arthritic changes.

I think it would probably be fair to say of subtrochanteric osteotomy that it gives a satisfactory functional result in most cases and delays, if it does not prevent, the onset of mechanical osteo-arthritis by improving the weight-bearing alignment.

A certain number of cases in 1920-30 were treated by a short period of traction in bed followed by the wearing of a caliper splint for a year or longer—or by a caliper only. I have only been able to trace a few of these cases and again the results are rather mixed. The longest follow-up was twenty-three years from the time of discarding the caliper. This man was in the county police and had no complaint of pain or stiffness for the past six or seven years. He had 10 degrees of fixed external rotation and no internal rotation movement therefore, but other movements were free and there was 1 in. of shortening. Radiographs showed deformity but no arthritic changes.

By contrast another man, sixteen years after discarding the caliper, complained of pain in the left knee and hip which limited activity. He had fixed external rotation deformity of 45 degrees and considerable limitation of all other movements of the hip. Radiographs showed deformity, loss of joint space and arthritic changes. Another man sixteen years after treatment was working as a market gardener and on his feet all day long without complaint. Abduction and internal rotation were limited and there was 1 in. of shortening. Radiographs showed much deformity but no definite arthritic changes.

A fourth man, also sixteen years after cessation of treatment, was a concrete worker and complained of pain in the hip only when he worked extra hard, and of stiffness after sitting for long. No recent radiograph of this case was obtainable.

These results, as far as they go, show that hips treated conservatively without operation can function satisfactorily for as long as approximately two decades, and that uncorrected deformity may exist for many years without radiographic evidence of arthritic changes. It is an indication that there must not be too much striving after anatomical perfection if it involves any risk of serious early impairment of function.

SUMMARY

The ideal, at which we should all aim, is early diagnosis of slipping of the upper femoral epiphysis before there is sufficient deformity to need correction. A slight backward rotation can be accepted as it will not materially affect subsequent function.

Osteotomy of the neck.—The technique of this method conforms to that just described in all particulars except that no attempt is made to identify and mobilize the epiphysial junction. A wedge of bone with base looking forward or upward according to the predominant deformity, is removed with a fine sharp chisel from the most prominent presenting portion of the neck, the resulting gap closed by abducting and internally rotating the limb, and a Smith-Petersen pin passed across the fracture line and well into the epiphysis. The cut sections of neck are often of slightly different diameter and do not appose perfectly leaving a slight step, but this does not seem to have any material effect on subsequent function and is not apparent in later radiographs.

Of the 9 cases treated in this way 5 were immobilized in plaster following operation, and 4 were pinned. The average follow-up period of the 5 plaster cases was eight years and the results are all classified as good. The follow-up period of the pinned cases is shorter ranging from one to three years, with an average of two years. 1 case is classified as excellent, and the other 3 as good. The majority of these cases have some shortening, but in no case exceeding 1 in. Most of them have some limitation of internal rotation and in some cases of flexion and abduction as well. Restoration of mobility of the affected hip was much speedier and rather more complete in the pinned cases than in those immobilized in plaster after operation.

CASE VI.—D. T. This was one of the cases with a long history (one year) of limp and gradual development of shortening and deformity of the left lower limb. Except

FIG. 16.—Slipped epiphysis and deformity of neck.

FIG. 18.—End-result three and a half years after operation.

CASE VI. (D. T.)

for some transient pain and stiffness of the left knee after a fall the patient made no complaint of pain whatever. His age was 15 at the time of admission to hospital on 28.4.42. He had then a fixed external rotation deformity of 45 degrees and flexion and abduction were limited but more from mechanical block than from muscle spasm. Radiographs showed slipping of the epiphysis and marked coxa vara deformity of the neck. It seemed obvious that nothing could be accomplished here by manipulation or traction and that a wedge osteotomy of the neck would be a better procedure than any attempt at mobilizing the already probably partly fused epiphysial junction. This was carried out on 1.5.42 and a pin inserted across the fracture line and well into the epiphysis. The patient was discharged from hospital six weeks later on crutches but weight-bearing was not allowed for seven months. The result is classed as good since the patient is doing heavy work as a farm labourer without any complaint of pain or disability whatever, but he has some limitation of flexion, and marked limitation of internal rotation and 1 in. shortening. Radiographs show a shortened, widened neck with approximately normal angle and some deformity of the head, which may lead to trouble in later life, but at present no evidence of avascular necrosis or of arthritis. This is a fairly typical end-result of this procedure. The absence of ischæmic changes following this operation is probably due to the clean division of the head allowing correction of deformity without exerting any leverage on the head.

DISCUSSION ON THE METHODS TO BE EMPLOYED IN ERADICATING TUBERCULOSIS OF BOVINE ORIGIN FROM THE HUMAN AND ANIMAL POPULATIONS

Mr. T. Dalling: *The control of bovine tuberculosis.*—The incidence of bovine tuberculosis in cattle in this country is high and its control must take a prominent place in the freeing of our herds from disease. Control and finally complete eradication of bovine tuberculosis are of major importance because of the effect of the infection from cattle sources upon the health of the human population as well as from the point of view of the general health of the cattle herds throughout the country. Attention in the past has been focused largely on the damage done to the human being from tuberculous infection of cattle origin. This has been all to the good and it is right and proper that we should view the problem of the tuberculous bovine from that angle: we must not forget, however, the large economic loss to farmers and to the State which arises from the high incidence of the infection in cattle herds and the comparative national prosperity that would accrue in the livestock world if tuberculosis could be well controlled or eradicated. The health of cattle has a definite relationship to the incidence of tuberculous animals in the herd: when a herd is freed from tuberculous infection the general health, apart from infectious diseases, improves markedly with consequent improvement in milk and meat yields.

In discussing methods of control and eradication due consideration must be given to circumstances pertaining in different countries; hence, it may be found that the same methods which were used in countries such as America and Finland, countries in which tuberculosis eradication is fully or almost fully completed, cannot be adopted in Great Britain.

Tuberculosis is spread among cattle mostly by direct contact from animal to animal: our methods of husbandry and housing are such that the presence in a herd of an animal excreting virulent tubercle bacilli will cause the spread of infection. It is noteworthy that the incidence of tuberculosis in a herd often varies with age-groups of animals, young stock which do not normally come into contact with adult animals having the lowest incidence: in many breeding herds in which infected animals are present the young stock is free from tuberculosis. Other methods of infection exist; for example, there is an increasing amount of evidence that bovine tuberculosis may be transmitted from an infected human being to cattle. The incidence of pulmonary tuberculosis in adult human beings due to infection with the bovine type may be greater than was at one time thought; it follows that "open" human infections may be of importance in the transmission of infection to cattle and due consideration must be given to spread by such means.

Control and/or eradication of tuberculosis in cattle may be attempted by several different methods. The following are examples: (a) The segregation of healthy calves

In treating these early cases the use of the Smith-Petersen pin does seem to be an advance on older methods since it shortens hospitalization, simplifies after-care and accelerates the curative factor of epiphysal fusion without causing material shortening of the limb. The functional results have been uniformly excellent.

When the epiphysal displacement has passed beyond acceptable limits, correction is desirable to prevent the coxa vara deformity which is liable to lead to the development of mechanical osteo-arthritis in later life. The better the anatomical correction, the better should be the prospect of prevention of arthritis, but if the chosen method causes ischæmic changes leading to severe restriction of hip movement the price must be considered too high. It is better to accept some uncorrected deformity, modified perhaps by the relatively simple operation of subtrochanteric osteotomy, which may result in a mobile and comparatively painless hip for two or three decades before arthritis develops, if it does at all, than to obtain a perfect anatomical correction but a stiff hip-joint within five years of manipulative reduction.

It seems clear from the results I have given, both English and American, that correction of epiphysal displacement by closed and still more by open manipulation at the epiphysal junction does entail a definite risk of causing avascular necrosis of the femoral head, and though the anatomical correction is almost perfect and many of the short-term functional results are good, I think that both these methods should be condemned.

Reduction by strong traction is safe if not maintained too long but, unless applied early, is not always effective in reducing displacement especially the backward rotation. If successful it should be followed by immediate pinning. If it fails and the deformity is considered severe enough to need correction this may be effected by wedge osteotomy of the neck of the femur and pinning, or at a later date, after fusion of the epiphysis has occurred, by subtrochanteric osteotomy. The comparatively short-term results of the former operation in my small series have been functionally good and no case has shown evidence of avascular necrosis of the femoral head. The anatomical correction is rather better than that obtained by subtrochanteric osteotomy. To justify the operation, however, it will have to be shown that the long-term results, especially as regards prevention of mechanical osteo-arthritis, are definitely better than those resulting from the simpler extra-articular operation.

DISCUSSION ON THE METHODS TO BE EMPLOYED IN ERADICATING TUBERCULOSIS OF BOVINE ORIGIN FROM THE HUMAN AND ANIMAL POPULATIONS

Mr. T. Dalling: *The control of bovine tuberculosis.*—The incidence of bovine tuberculosis in cattle in this country is high and its control must take a prominent place in the freeing of our herds from disease. Control and finally complete eradication of bovine tuberculosis are of major importance because of the effect of the infection from cattle sources upon the health of the human population as well as from the point of view of the general health of the cattle herds throughout the country. Attention in the past has been focused largely on the damage done to the human being from tuberculous infection of cattle origin. This has been all to the good and it is right and proper that we should view the problem of the tuberculous bovine from that angle: we must not forget, however, the large economic loss to farmers and to the State which arises from the high incidence of the infection in cattle herds and the comparative national prosperity that would accrue in the livestock world if tuberculosis could be well controlled or eradicated. The health of cattle has a definite relationship to the incidence of tuberculous animals in the herd: when a herd is freed from tuberculous infection the general health, apart from infectious diseases, improves markedly with consequent improvement in milk and meat yields.

In discussing methods of control and eradication due consideration must be given to circumstances pertaining in different countries: hence, it may be found that the same methods which were used in countries such as America and Finland, countries in which tuberculosis eradication is fully or almost fully completed, cannot be adopted in Great Britain.

Tuberculosis is spread among cattle mostly by direct contact from animal to animal: our methods of husbandry and housing are such that the presence in a herd of an animal excreting virulent tubercle bacilli will cause the spread of infection. It is noteworthy that the incidence of tuberculosis in a herd often varies with age-groups of animals, young stock which do not normally come into contact with adult animals having the lowest incidence: in many breeding herds in which infected animals are present the young stock is free from tuberculosis. Other methods of infection exist; for example, there is an increasing amount of evidence that bovine tuberculosis may be transmitted from an infected human being to cattle. The incidence of pulmonary tuberculosis in adult human beings due to infection with the bovine type may be greater than was at one time thought: it follows that "open" human infections may be of importance in the transmission of infection to cattle and due consideration must be given to spread by such means.

Control and/or eradication of tuberculosis in cattle may be attempted by several different methods. The following are examples: (a) The segregation of healthy calves

from tuberculous adults and their rearing under conditions which prevent them from becoming infected. (b) The detection of all infected animals and their disposal, healthy, non-infected animals being maintained during the clean-up under conditions which will preserve their freedom from infection. (c) The creating by vaccination of a resistance or immunity to bovine tuberculosis. (d) The treatment (curative) of infected cattle which are considered worth treating.

It may be that a combination of two or more of these methods should be considered.

To attempt, as has been suggested, to slaughter all known infected cattle would so deplete the country of milk-producing stock that serious consideration can never be given to it. Measures will have to be adopted whereby the disease is controlled to a greater extent than it is to-day with the object in view of its final eradication. This will mean a long programme. Attempts are even now being made to control tuberculosis on a herd basis; this can, however, be carried out only in self-contained herds in which movement of stock is very limited. It will be necessary to extend the system of tuberculosis control to areas, some small, as a beginning, with a gradual linking of the areas until the country is covered. Removal of infected cattle from herds and areas is the important break in the further infection of the animals in question; their disposal, however, is of even greater importance. Mr. Ritchie will refer more fully to this point. There may be something to be said for Sir William Savage's view that there should exist special herds in which infected cattle can be collected and where they can be maintained so long as they are of economic value. It may be that an extension of the herd scheme which he has suggested to areas would provide an answer to the question of disposal of infected animals.

No matter which method of control is ultimately decided upon, the diagnosis of the infected animal is all-important. The present method is by the use of tuberculin, injected intradermally, with the reading of the resulting reaction some days later. The diagnosis of bovine tuberculosis must depend on the use of tuberculin; up to the present we have not been able to devise any more reliable method. The type of tuberculin which we are using to-day differs very considerably from that used a few years ago. It is now a comparatively simple procedure to prepare purified protein derivative (P.P.D.) which contains at least 90% of tuberculo-protein produced during the growth of tubercle bacilli on liquid medium which itself contains no protein; this is the so-called "synthetic medium" in which asparagine is the source of nitrogen. By simple chemical treatment of the filtrate the purified tuberculo-protein is made available.

Tuberculin testing is a somewhat complicated procedure for we have now much evidence that no tuberculin yet prepared is specific for the diagnosis of one single type of tuberculous infection, and, further, that cattle can become sensitized by a variety of agents which renders them reactive in different degrees to different "tuberculins". In discussing tuberculin we have to consider the acid-fast group of organisms as a whole. We find in studying the "tuberculins" produced from them that each has both a homologous and a heterologous specific factor. For purposes of discussion tuberculins can be divided into groups of which the most important from our point of view are those derived from tubercle bacilli of mammalian and of avian origin. Tuberculins from human and from bovine strains of tubercle bacilli contain tuberculo-protein rich in mammalian specificity and lower in avian specificity. The relationship factor is roughly 1 to 20-40. Within the mammalian group the relationship between the specific factors of human and bovine strains is roughly 1 to 2. Thus, it would seem a comparatively simple matter to differentiate between bovine and avian sensitivity by the use of the respective tuberculins. Unfortunately this does not hold good; cattle are relatively insensitive to any tuberculin when compared with the sensitized guinea-pig or the human being and comparatively large amounts of tuberculo-protein are required to elicit any reaction in them no matter what their state of sensitivity. It will therefore be evident that the differences in the reactions produced by these two tuberculins has led to some confusion. There has, however, been worked out a scheme of testing whereby reasonable accuracy is obtained especially when the herd-testing history is known.

Modern tuberculins are tested for potency and specificity and are compared with "standards". Sensitized guinea-pigs are used for such work, sensitization being accomplished by actual infection of the animals with specific strains of *M. tuberculosis*.

One great advantage in using P.P.D. is that it is possible with a minimum of trouble to ensure that tuberculin of similar potencies and specificities can be used at all times and thus operators can compare results on the same animals no matter at what intervals the successive tests are carried out.

Work is in progress in attempts to increase the specificity of tuberculin. There are indications that by chemical means it may be possible to prepare more highly specific tuberculins: until such preparations are available it will be necessary to continue to use the so-called "comparative" test, i.e. the simultaneous injection of mammalian and avian tuberculins.

Some attention has been given to the immunization of cattle against tuberculosis and to its place in the control of tuberculosis. Although our work has progressed within recent years we have not yet reached the stage when we can give a definite opinion on the place of vaccination in the control of the disease in the field. It will be recalled that the B.C.G. culture of bovine tubercle bacillus, elaborated some years ago by the French workers, has been the subject of experimental research in many countries and that workers in this country have also included it in their studies. We have already reported at meetings of this body and in the scientific press the results of laboratory and semi-field experiments in which it was shown that repeated intravenous injections of a suspension of the culture set up a resistance to artificial infection with bovine tubercle bacilli at a later period. It became necessary to examine the use of the cultures under field conditions and for this work the Agricultural Research Council organized a field trial which includes about 100 farms. The main object of the trial is to ascertain in how far the use of B.C.G. vaccine can assist a farmer in the changing of his herd from one containing many cattle infected with tuberculosis (as shown by their being positive reactors to the tuberculin test) to one free from tuberculosis. The trial is of a simple nature. A survey of the incidence of tuberculosis in the whole herd is made (tuberculin testing) before the herd is accepted for inclusion in the trial. Only herds in which the incidence of tuberculosis is high are selected and in which the young stock are comparatively free. Only calves and young unbred stock which fail to react to the tuberculin test are included in the trial.

Every six months a dose of the culture suspension is injected intravenously. As the young stock reach maturity and are in milk production they are brought into the milking herd and an equal number of the original cows are disposed of: hence, in a period of time which varies with the size of the herd the milking-herd consists entirely of vaccinated animals. At this stage vaccination ceases. It is hoped that by this means farmers who are not in a position to adopt other means of clearing their herds of tuberculous infection will be able to have a clean herd in a minimum of time. An objection to the method is that the injection of the culture is followed by a sensitivity to tuberculin; our finding, however, is that the sensitivity to mammalian tuberculin is of comparatively short duration and that within 9 to 12 months following the cessation of vaccination, vaccinated animals are considered free from bovine tuberculosis so far as the tuberculin test is concerned. It is as yet too early to give an opinion on the usefulness of this method as an adjunct to controlling tuberculosis; we shall not be in a position to make any statement for probably two years. We can at this stage, however, say that a few herds in the trial now consist entirely of vaccinated animals and that they have been accepted as T.T. herds under the Milk Designations Order.

The use of B.C.G. vaccine is not without some risk. We have experienced some peculiar "reactions" following the injection of the vaccine, a few of which have been alarming. While we were prepared to find some disturbances of health and actual deaths immediately following the injection of the culture, we were somewhat surprised to meet a peculiar delayed reaction in which respiratory distress, marked emaciation and lameness were prominent and occurred at any time up to three or four weeks following an injection. These reactions are not confined to the first injection but have been noted following injections at all stages of the trial. The number is comparatively small and not confined to one farm or group of farms but may affect one or more animals in different parts of the country.

Preliminary experiments indicated that suspensions of the vole acid-fast organism injected intravenously into cattle gave rise to a resistance to bovine tuberculosis of an order equal to or even higher than that obtained with B.C.G. Work with this organism is still in progress and the results are not yet sufficiently advanced to make any further statement on its usefulness as an immunizing agent. It will be some little time before the experiments warrant a field trial.

References to the literature show that many attempts are being made to evolve methods of effecting cures of bovine tuberculosis by the use of chemical compounds. If success attends the investigators' work by the finding of suitable products for this purpose there is little doubt that a high place will be found for such treatments in human medicine. Doubtless, also, there would be some who would advocate similar treatment for affected cattle. There must be, however, in the minds of many of us some grave doubts of the

from tuberculous adults and their rearing under conditions which prevent them from becoming infected. (b) The detection of all infected animals and their disposal, healthy, non-infected animals being maintained during the clean-up under conditions which will preserve their freedom from infection. (c) The creating by vaccination of a resistance or immunity to bovine tuberculosis. (d) The treatment (curative) of infected cattle which are considered worth treating.

It may be that a combination of two or more of these methods should be considered.

To attempt, as has been suggested, to slaughter all known infected cattle would so deplete the country of milk-producing stock that serious consideration can never be given to it. Measures will have to be adopted whereby the disease is controlled to a greater extent than it is to-day with the object in view of its final eradication. This will mean a long programme. Attempts are even now being made to control tuberculosis on a herd basis; this can, however, be carried out only in self-contained herds in which movement of stock is very limited. It will be necessary to extend the system of tuberculosis control to areas, some small, as a beginning, with a gradual linking of the areas until the country is covered. Removal of infected cattle from herds and areas is the important break in the further infection of the animals in question; their disposal, however, is of even greater importance. Mr. Ritchie will refer more fully to this point. There may be something to be said for Sir William Savage's view that there should exist special herds in which infected cattle can be collected and where they can be maintained so long as they are of economic value. It may be that an extension of the herd scheme which he has suggested to areas would provide an answer to the question of disposal of infected animals.

No matter which method of control is ultimately decided upon, the diagnosis of the infected animal is all-important. The present method is by the use of tuberculin, injected intradermally, with the reading of the resulting reaction some days later. The diagnosis of bovine tuberculosis must depend on the use of tuberculin; up to the present we have not been able to devise any more reliable method. The type of tuberculin which we are using to-day differs very considerably from that used a few years ago. It is now a comparatively simple procedure to prepare purified protein derivative (P.P.D.) which contains at least 90% of tuberculo-protein produced during the growth of tubercle bacilli on liquid medium which itself contains no protein; this is the so-called "synthetic medium" in which asparagine is the source of nitrogen. By simple chemical treatment of the filtrate the purified tuberculo-protein is made available.

Tuberculin testing is a somewhat complicated procedure for we have now much evidence that no tuberculin yet prepared is specific for the diagnosis of one single type of tuberculous infection, and, further, that cattle can become sensitized by a variety of agents which renders them reactive in different degrees to different "tuberculins". In discussing tuberculin we have to consider the acid-fast group of organisms as a whole. We find in studying the "tuberculins" produced from them that each has both a homologous and a heterologous specific factor. For purposes of discussion tuberculins can be divided into groups of which the most important from our point of view are those derived from tubercle bacilli of mammalian and of avian origin. Tuberculins from human and from bovine strains of tubercle bacilli contain tuberculo-protein rich in mammalian specificity and lower in avian specificity. The relationship factor is roughly 1 to 20-40. Within the mammalian group the relationship between the specific factors of human and bovine strains is roughly 1 to 2. Thus, it would seem a comparatively simple matter to differentiate between bovine and avian sensitivity by the use of the respective tuberculins. Unfortunately this does not hold good; cattle are relatively insensitive to any tuberculin when compared with the sensitized guinea-pig or the human being and comparatively large amounts of tuberculo-protein are required to elicit any reaction in them no matter what their state of sensitivity. It will therefore be evident that the differences in the reactions produced by these two tuberculins has led to some confusion. There has, however, been worked out a scheme of testing whereby reasonable accuracy is obtained especially when the herd-testing history is known.

Modern tuberculins are tested for potency and specificity and are compared with "standards". Sensitized guinea-pigs are used for such work, sensitization being accomplished by actual infection of the animals with specific strains of *M. tuberculosis*.

One great advantage in using P.P.D. is that it is possible with a minimum of trouble to ensure that tuberculin of similar potencies and specificities can be used at all times and thus operators can compare results on the same animals no matter at what intervals the successive tests are carried out.

milking cow as far as possible, the incidence can be greatly reduced. In such a herd it will be recognized that removal of clinically infected cows, particularly those giving tuberculous milk, is of very considerable value.

In this country, it is usually found that in a herd which at its first test shows no reactors to the tuberculin test the method of management has closely followed the one outlined above. Such herds are not so frequently found nowadays, as many of them have already been tested and have become recognized as tubercle-free herds. It is still very common, however, to find a herd in which there is a high incidence of disease among the cows whereas the young stock are practically all free of infection. Owners of such herds can often be persuaded to remove all the cows from the herd, to replace them by cows from attested herds, and thus establish a clean herd, as it were, overnight. The non-reacting young stock are retained. In one or two parts of the country this practice is frequently followed, and if care is taken to clean and disinfect the cow sheds and buildings thoroughly before the new cows are introduced, remarkably good results have been seen at subsequent tuberculin tests. Even in fairly valuable pedigree herds, owners are often not averse to this method as they are able, by retaining their non-reacting young stock, to maintain breeding lines which may be of considerable value to them. It has been found that the subsequent history of the herds as regards reactors is invariably good and the owners maintain that the financial benefits from this rapid eradication are considerable. In this type of herd it is possible to eradicate the disease without immediately disposing of the reactors. Where an owner has two sets of farm buildings, it is usually a simple matter to segregate the non-reactors from the reactors. The reactors are kept in separate buildings and are disposed of as opportunity offers and replaced by non-reactors and their shed can come into use for free stock after suitable preparation. By segregation of non-reactors and reactors on the same farm or even in the same shed this procedure may also be followed but the difficulties are greater. When this method of segregation of reactors and retention of all non-reactors is followed, the subsequent history of the herd is seldom so good; at the herd retests, which should be done some sixty days after the initial test, it is not uncommon to find a fairly high percentage of reactors among the non-reactor group. A few reactors will be found in many herds at the third or even subsequent herd tests, and I have known cases where, as testing proceeded, all the non-reacting cows at original test have eventually been removed as reactors.

A possible modification of this method may one day become available if either of the methods of vaccination at present under test proves satisfactory. An effective vaccine has a limited practical application, however. It is of no value in flying herds, which are often most heavily affected; if calves have already become infected, for instance from tuberculous milk, its full advantage is lost.

The first test of the herd is of prime importance; unfortunately, it is usually found to be the most unreliable. It was in herds tested for the first time that we found so many tuberculous animals which failed to show reactions at the normal times of observation. Late positive reactions have not been so often encountered since the potency of the tuberculin has been increased, but it is still not uncommon to find, in animals tested for the first time, that no response to tuberculin is seen until the ninety-sixth hour after injection. It is essential in the employment of the tuberculin test in cattle to recognize the fact that it has greatest value if it is employed as a herd test. This is more than ever important in assessing the results of the comparative test, which has already been mentioned. In the initial test of a herd, the first essential is to be sure that all clinical cases which can possibly be recognized have been removed, to avoid the tremendous risk of retaining as a non-reactor the grossly diseased animal which does occasionally fail to react. The results of the test should then be assessed on the basis of deciding the fate of the animals in groups designated with reference to their common housing, grazing and general contact. If a clinical case has been found in any group showing a high percentage of reactors, say, 50%, it is unwise to retain any of the non-reacting animals in that group and, indeed, it is probably good practice to recommend to an owner to dispose of the non-reactors in a group of cattle unless there are less than 20% reactors in that group. A number of reactors among young calves, for instance, almost invariably indicates that a cow in the herd is excreting tubercle bacilli and the calves have become infected from her milk; if this cow has not already been recognized, she should be sought for, and it is unwise to confine the search to the reacting cows entirely, although she will usually be found among them. Having decided which animals are to be removed and how the effort to establish a free herd is to proceed, it is essential to carry out periodical tests of the non-reactors, whether the reactors have all been removed from the farm or are in isolation on some portion of it.

place which even the perfect curative treatment could occupy in the control of tuberculosis in cattle. Our policy must be one of prophylaxis rather than curative treatment, for a minimum of imperfectly treated animals in a herd or an area would be fatal to any control or eradication scheme. We feel strongly that too great emphasis must not be given to the adoption of curative methods and that plans must be laid in other directions.

No matter which method or combination of methods is to be adopted the eradication of bovine tuberculosis from the herds in this country must of necessity be a long-term policy. That, of course, is no reason why, after careful planning, a beginning should not be made on a fairly wide scale at an early date. We must take due notice of the fact that the large majority of calves are born free from tuberculous infection and can be so maintained, that there are already in the country areas in which the incidence of tuberculosis is quite low, and that for all practical purposes this country is self-contained so far as cattle are concerned.

The points for discussion, as I see them, are the following: (1) How to ensure that young, healthy stock can be kept free from tuberculosis; (2) the possibilities of creating areas free from the disease, of maintaining healthy cattle in them, and of extending such areas until finally the whole country is covered; (3) the disposal of infected cattle; (4) improvements in our present methods of diagnosing tuberculosis; (5) vaccination as an adjunct to methods of control and eradication.

Mr. J. N. Ritchie: Where success in eradication of tuberculosis in cattle has been achieved, the tuberculin test and disposal of reactors has been the method employed.

Some form of intradermal test is used in practically every country nowadays. In Great Britain, we use the double intradermal test, and since 1940 have injected two tuberculins, mammalian and avian, into selected sites in the neck. By comparing the reactions produced by the two tuberculins, it has been found possible to recognize those animals sensitized by the bovine type of organism and those sensitized by some other related organism; this is of great practical importance, since only the bovine type organism produces progressive disease in cattle. This comparative test has been found extremely useful when used as a herd test; for testing individual animals it has less value, but it is not alone among tuberculin tests in this respect.

We recognize five organisms which sensitize cattle to mammalian tuberculin: *Mycobacterium tuberculosis* of bovine, human and avian types, *Mycobacterium johnei*, and an acid-fast organism associated with lesions in the skin. There is some evidence that the actinobacillus may also sensitize and a suspicion that other organisms may also be involved. It is not difficult to recognize the reactor sensitized by the avian type organism or by the Johne's bacillus: it is more difficult to recognize the reactor sensitized by the organism associated with skin lesions unless the lesions have been observed. It is extremely difficult to differentiate the reactor sensitized by the human type from the one sensitized by the bovine type of tubercle bacillus. When there is a suspicion from the history of the herd, and of the people who are in close contact with it, that a human source of infection is present, it may be necessary to retest reactors even though the test suggests that a bovine type of organism is involved. The sensitization from the human type of organism is usually comparatively fleeting and this fact may often allow a differentiation at the time of retest. However, it must be remembered that infection from a human source is not necessarily from the human type of organism but may well be from the bovine type. Some form of comparative test must be used until a more specific tuberculin can be produced.

Removal of clinical cases from a herd, unassociated with other efforts of control, makes only a slight contribution to the elimination of infection.

Removal of clinical cases is, of course, of value from the public health point of view and the efforts which have been made to remove clinical cases have been aimed mainly at reducing the weight of infection in the milk supply. In this connexion, sampling of bulk milk for biological test and further investigation on the premises supplying positive samples might well be increased with advantage.

Care in herd management based on recognition of the fact that very few calves are born infected can contribute greatly to success in control within the herd. Only a small percentage of young cattle is infected and, in general, it is at the stage when a milking heifer is introduced to the dairy herd that she picks up her primary infection. Where care is taken to maintain the young stock separate from the cows and segregate the young

already been done, and the numbers of animals slaughtered under the Tuberculosis Order in each county since 1925. In 1938-39 survey tests were made on selected self-contained herds. In all, 364,286 cattle were tested and revealed 13% reactors. Because of the method of selection of the herds, and the fact that more testing was done in districts where good results were obtained, this figure cannot be taken as a reflex of the position throughout the country but, if the figures are studied more closely county by county, and in conjunction with the other factors which can be taken into account, a much more accurate estimate can be reached. The survey tests in England gave a percentage incidence of reactors of 14.1%. In eight counties showing an incidence of reactors of over 25%, 14,300 cattle were tested from a population of 1,148,646; whereas where less than 10% reactors were found 51,315 cattle were tested from a population of 1,305,450. This in itself suggests that the incidence figure for the country is too low. Adjusting the figures for each county in the light of the numbers slaughtered under the Tuberculosis Order and the numbers now in tubercle-free herds I have reached a figure of 20% as the approximate incidence of reactors in England. In Wales, the survey test showed 4.1% reactors among 116,082 cattle tested. Some counties showed an extremely low incidence and in them there are now large numbers of attested herds so that this factor has not reduced the incidence markedly from the survey test figure. On the other hand, there are one or two counties with large numbers of flying herds with a heavy infection and by adjustments on a county basis the incidence appears to be in the region of 7.5%. The herds surveyed in Scotland showed 23.1% reactors. The indication of the weight of infection county by county as revealed by the Tuberculosis Order figures very closely conforms with the test survey figures. However, the response to the Attested Herds Scheme in Scotland has been good and in some counties extremely so; there are high percentages of attested cattle in several counties where the incidence was high as revealed by the survey test and consequently the incidence in the country has been considerably reduced since the time of the survey. It is now probably about 14%.

Throughout Great Britain I have estimated the percentage of reactors to be between 17 and 18% of all the cattle. This represents a probable 30 to 35% infection among cows, so that in view of recent reductions in incidence by the eradication of infection from many herds, the estimate of 40% infection among cows may not have been very high at the time it was made.

Sir William Savage (*in absentia* read by Dr. A. Haddow): While the eradication of tuberculosis in bovines is essentially a veterinary problem the fact that many cases of tuberculosis in man are of bovine origin makes us, on the medical side, vitally interested in the problem.

Certain facts, I suggest, are incontrovertible. One is that tuberculosis in cows in Great Britain is very extensive, although irregularly distributed. Secondly, all measures, apart from the use of tuberculin to obtain tuberculosis-free herds, are unscientific in conception, and so doomed to failure. Thirdly, any system of eradication of tuberculosis in bovines must be a long-term one and, even if completely successful eventually, cannot in the meanwhile prevent much milk infection with tubercle bacilli and much human disease if the milk or milk products are consumed raw. Knowing that the price of delay is a heavy annual toll of human deaths from bovine tuberculosis and a still larger toll of crippling disease, the various bodies representing medical and Public Health interests have passed resolutions insisting upon the urgent need for the compulsory pasteurization of our milk supplies. Prolonged and detailed investigations have established that pasteurization causes no material damage to the nutritive qualities of milk and that when effectively carried out it renders milk free from the risk of carrying pathogenic bacteria. The only difference of scientific opinion which exists is whether the whole of the milk supply should be pasteurized, or if an exception should be made for milk from herds free from tuberculosis. In view of the risks from other pathogenic bacteria in milk those who hold the first view are scientifically justified, but since the risk from the tubercle bacillus is so much the greater many of us are content to permit, at least for the present, milk from tubercle-free herds to be sold raw. This compromise should facilitate the eradication of bovine tuberculosis.

In the eradication of tuberculosis in bovines, the chief problem is the "reactor". Four methods have been considered. One is to slaughter without compensation, but as it is obviously unfair and impracticable it needs only mention. Another is to slaughter and

Frequent testing of herds at the early stages and following any degree of reinfection is the basis of the system in the Attested Herds Scheme. A herd does not become officially attested until no reactors have been found at three successive tests. After a herd has become attested, retests are done at annual intervals so long as no reactors are revealed; but if the herd has been reinfected, a retest is done sixty days after reactors have been disposed of, and this is repeated so long as reactors are found; after the first test showing no reactors, a test is done in six months, and then the herd reverts to the normal annual test. Various important rules must be observed, in addition, to maintain a herd tubercle-free. Purchased stock must not be added to the herd unless from another attested herd or, if not from such a herd, until after having passed a test and having been isolated for sixty days and retested. The herd must be isolated from other stock, and this may mean double fencing on the boundary of the farm. No milk from untested sources is fed to calves unless sterilized. By this frequency of testing and with the rules in force, the attested herds in this country show an incidence of reactors of approximately 0.5% of the cattle tested; and there are some 20,000 attested herds comprising approximately 750,000 cattle in Great Britain. In view of curtailment of the work during the war period progress has been remarkably good, but it is clear that some more effective means must be sought of increasing the number of tubercle-free herds without proportionately increasing the amount of work involved in maintaining them free.

One method that commends itself is eradication of the disease from defined areas of the country, and for this method authority is contained in the Agriculture Act, 1937, by which the Minister may declare eradication areas and slaughter reactors when a substantial proportion of the cattle in an area is free from disease. There are many advantages in area eradication. The work of supervision and testing the 20,000 attested herds in this country has now become extremely heavy. On the average, the herds are tested one and a half times per annum, and if eradication is to proceed it would be a colossal task to maintain that frequency of testing throughout all the herds; at present, because of the risks of reinfection, this frequency must be maintained, but it is already being shown that where large numbers of herds contacting each other in a district are attested, the percentage of reactors is lower because the risks of reinfection are less. We have the American experience where herds in which no reactors are found are tested at from three to six years. If we can establish tubercle-free areas we can, after the initial stages, increase the interval after a clear test from the present twelve months to three years, and thus reduce the amount of work and release staff for districts which are in need of it. In a free area, it would be much easier for herd owners who at present have to take a variety of careful precautions against neighbouring infected herds. It would also be possible to allow free inter-herd movement of cattle inside the area instead of requiring that all movements must be on the authority of a permit issued to the owner.

The 20,000 attested herds in Great Britain, comprising approximately 750,000 cattle, represent about 9% of the total cattle. In England 4.24%, in Wales 19.52%, and in Scotland 21.8% of cattle are in attested herds. In England, the highest county figures are 15.4 in Berkshire, and 14.1 in Surrey, with only two other counties showing over 10%. In Wales, the highest figures are Carmarthen 49.6, Cardigan 48.3, Merioneth 34.3, Pembroke 28.8, with two other counties over 10%. In Scotland, Bute has 75.4% attested cattle, Ayr 66.3, Kirkcudbright 46.5, Dumfries 45.2, Lanark 43.5, three other counties over 30%, three over 20%, and seven over 10%. There are some districts in Scotland and Wales, then, which have progressed sufficiently to suggest that, on the consideration of the weight of infection in them, area eradication might reasonably commence in a comparatively short time. It would be necessary, before declaring areas, however, to ensure that this method was adopted with a reasonable prospect of development from one area to another, until gradually the whole country was covered. It would be necessary to ensure that the areas were large enough to provide within them all the facilities, such as markets for the owners in the area, and also that they left such facilities still available to owners who remained outside the area.

The incidence of tuberculosis in cattle in Great Britain cannot be closely estimated, as there is not sufficient evidence of tests of large numbers of cattle throughout the country. The most commonly quoted figure is that 40% of cows are infected, but that figure is based largely on slaughterhouse returns, and is certainly too high, but it was estimated, of course, when there were very few tubercle-free herds in this country. With the evidence which is available, I have attempted to reach an estimate of the incidence. I have taken into account the number of cattle, approximately 750,000, in attested herds and the number, approximately 140,000, in T.T. herds which are not attested (these latter cattle show a percentage of reactors of about 2%), the evidence of survey testing which has

already been done, and the numbers of animals slaughtered under the Tuberculosis Order in each county since 1925. In 1938-39 survey tests were made on selected self-contained herds. In all, 364,286 cattle were tested and revealed 13% reactors. Because of the method of selection of the herds, and the fact that more testing was done in districts where good results were obtained, this figure cannot be taken as a reflex of the position throughout the country but, if the figures are studied more closely county by county, and in conjunction with the other factors which can be taken into account, a much more accurate estimate can be reached. Sir Merrik Burrell: The theoretically fine idea of forming tuberculosis-free areas was most carefully examined by the Committee on Animal Diseases whose report was published some twelve years ago. The foundation of British agriculture is livestock. The cattle population of these islands is maintained by a continuous flow of hundreds of thousands of animals from the breeding areas in the wetter belt in the west, including Ireland, to the Midlands and to the dry cereal belt extending from Nairnshire to Norfolk, with the Devon cattle coming up into Hampshire and Sussex. No importing area of any extent could survive without this migration. Any attempt to stop it would disrupt the whole store cattle trade and with it the supply of milk and of beef. But it is possible to form closed areas in the exporting areas where the farms are small, the cattle population comparatively sparse in the mountain sheep districts, and in the county of Ayr. These would form pools of healthy cattle from which the attested herds in open areas could be recruited. The difficulties of hermetically sealing an importing area are immense, as any who has had to deal with sheep scab knows. The smuggling of cattle from Eire into Ulster during the war is a further instance of the hopelessness of the task.

I am not surprised at a considerably higher incidence of bovine tuberculosis in rural areas as compared with urban. Much of the milk in the former is peddled round the villages and scattered cottages by small producer-retailers. The bigger producer-retailers with well-established businesses founded on a hard-won reputation sell some of the best milk put on the market, but not so these little rural men. They buy all the cheap "screw" cattle in the markets, their premises are often badly constructed and dirty, and their methods bad. They are seldom, if ever, visited by the sanitary authorities and their milk analysed, and they escape all the controls to which the farmer selling to the wholesale buyer has to submit.

Attested herds alone, closed areas alone, will not eradicate tuberculosis entirely, but both methods pushed forward vigorously, with better prices for the better milk, will in conjunction go a long way to achieve success.

Mr. J. W. Salter Chalker: Speaking as Chairman of the Diseases of Animals Committee of the National Farmers' Union I would like to say that the farming community view very seriously the subject under discussion. They are not only concerned because of the part bovine tuberculosis plays in the general economy of animal husbandry but are particularly anxious that the milk supply in every way and particularly in this respect should enjoy the confidence of the public and the medical profession.

The problem as indicated by Professor Dalling and Mr. Ritchie is a very large one. It is not a responsibility which the agriculturist should be expected to shoulder on his own. It is unfortunate and very unfair that so often when the question is referred to in the Press it should be expressed in terms reflecting unfavourably on the farmer.

Farmer pioneers who sought to eradicate tuberculosis from their herds before the Ministry's Attested Herds Scheme was introduced received only meagre compensation for their public-spirited action; they received no real measure of support from the Ministry, the dairyman or the consumer, in so much as they only received a premium on the very small proportion of their production which was purchased by the public as T.T. milk.

The Ministry's Attested Herds Scheme was a considerable step forward and it was unfortunate that at the outbreak of war it was found necessary to withdraw it. Its later reintroduction with a premium on the whole production of milk from T.T. licensed herds was indeed welcome and has meant considerable progress in numbers of attested herds. However this is as it is, the farmer to-day is not satisfied with this progress and a resolution was passed at the last meeting of my Committee requesting me to approach the President of the Union in order to seek an interview with the Minister of Agriculture as to the urgency of starting the attested free area scheme at the earliest possible moment.

Bovine tuberculosis is a national responsibility and the farming community are prepared to play their full part in its eradication.

Dr. W. M. Crofton said that the most hopeful thing that he had heard during the discussion was the fact that extensive trials were being made of preventive inoculation, which, he considered, was the only hope for the elimination of tuberculosis, both in domestic beasts and in the human population. He did not think, however, that a live antigen such as B.C.G. was the proper material to use. Live antigens for prophylaxis were not as efficient as dead antigens because live antigens were energetically precluded by the endothelial cells of the capillaries from getting to the healthy tissues of the body,

pay compensation as is done in U.S.A. and Canada. This is possible there as the incidence of tuberculosis is about one-tenth of ours, but financially impracticable here while also very wasteful. A third plan is to brand the reactor and then let loose for the owner to do what he likes with him. I see considerable drawbacks in this plan and it is a very controversial veterinary problem. The fourth procedure is the one now operative, i.e. to turn out of the herd unmarked and unsupervised. This often simply means a transference from one herd to another and is a profoundly unsatisfactory procedure.

In my Mitchell Lecture delivered in 1933 (*Brit. med. J.* (ii), 905) I suggested another method, which although it has had lip-service approval has never been put into practice. As I still consider this is the right, and indeed the only satisfactory, way to deal with the reactor I reproduce my essential points:

"The reactors with no clinical signs are mostly in good health, giving normal milk, and are not excreting tubercle bacilli or only very occasionally. There is considerable evidence that the majority of these animals, if placed under good conditions, show little or no progressive tuberculosis, and will for long periods yield normal milk free from tubercle bacilli. If their milk can be safeguarded, and if they can be prevented from infecting other cows, why slaughter such valuable animals? The scientific method is to keep the reactors together upon separate farms containing nothing but reactors. Periodical veterinary inspection would weed out any becoming clinical cases, and the cows would have to be kept (as all cows should be) under good open-air conditions. I see no objection to their milk being sold for human food in the open market, after being subjected to efficient pasteurization. Regular bacteriological tests, before and after pasteurization, would soon demonstrate the validity as regards the safety factor of any such scheme. The cows would produce calves in the ordinary way, and if the calves were brought up on Bang's principles and segregated in their own buildings and fed on heated milk they would grow up non-reactors, and would serve as that very necessary thing—a storehouse of non-reacting cows to complete the herds of non-tuberculous cows depleted by the removal of reactors.

"The price paid to an owner for the reacting animal should be the price of a damaged cow, since obviously a cow infected with tuberculosis is not worth the price of a healthy cow. The exact figure is a matter for discussion, but as a basis of argument it might be called a two-thirds value, thus making the owner lose something like his share under the United States of America scheme. It may be suggested that such a herd of reactors with veterinary inspections, bacteriological tests, and pasteurization would necessitate milk charges above the normal economic price. The bacteriological testing should be done free by the County Public Health Authorities as their share, while they would naturally supervise the pasteurization. In view of the fact that the herd only costs two-thirds of one of healthy animals. I believe the milk could be produced at current rates. The herds would naturally be of considerable size.

"Under my proposals, instead of numerous herds made up of a mixture of reactors, and non-reactors as at present, there should be herds in which the cows were non-reactors and herds in which they were all reactors".

Every veterinary surgeon knows how rapidly tuberculosis will spread from an infected animal introduced into a tuberculosis-free herd, and separate herds seem simple common sense.

In actual fact we get this sort of thing now but under the worst possible conditions. A producer of "Accredited" milk lured by the higher bonus for "T.T." milk has his herd tested, and finds a large proportion are reactors. He removes the non-reactors to new premises and starts them as a T.T. herd. He leaves the reactors in his existing herd and continues to sell the milk from these cows, all of which are tuberculous, as *Accredited* milk and to sell it *raw*. This is perfectly legal and I have had officially to pass many such cases. The division into two herds is as I suggest, but instead of the reactor herd milk being pasteurized and the animals rigidly supervised it is sold *raw* and as a superior quality milk under the designation "Accredited".

I suggest that the provision of herds free from tuberculosis would be greatly speeded up if my solution for the reactor problem was adopted in practice. Given the necessary legal power I cannot visualize any serious practical difficulties.

Section of Dermatology

President—SYDNEY THOMSON, M.D.

[December 20, 1945]

Pityriasis Rubra Pilaris with Ainhum and Syringomyelia.—K. TATZ, M.R.C.S., L.R.C.P.
(for H. W. BARBER, M.B.).

R. G., aged 51 years. Family and personal history uneventful until 1917 when he developed keratoderma of the palms and soles. About two years later, there developed a scaly rash on his arms and legs which was diagnosed as psoriasis at the time. At about the same time, there developed ainhum-like constrictions and deep painful fissures on his palms and fingers. Six years ago a fissure at the base of his left thumb deepened to such an extent that the thumb fell off; this was not accompanied by any pain. During the next five years the remaining four fingers of the left hand were lost.

In 1944 he had difficulty in moving his left shoulder. X-ray revealed a Charcot joint and a diagnosis of syringomyelia was made.

On examination the patient shows marked keratoderma of the palms and soles. The thumb and distal halves of the fingers of the left hand are missing. All the fingers of the right hand have deep ainhum-like constrictions encircling them. On the forearms, legs and knees there are patchy, scaly psoriasiform areas. On the back of the wrist and fingers there is some follicular hyperkeratosis. The face and scalp are not involved.

Neurological examination reveals typical signs of syringomyelia.

Plasma protein and hippuric acid tests normal.

Blood carotene and blood vitamin A normal.

Biopsy from the back of the hand showed changes compatible with pityriasis rubra pilaris.

Comment.—This is a case of a man who developed keratoderma and fissures with ainhum-like constrictions and a psoriasiform lesion twenty years before the development of syringomyelia with subsequent loss of the fingers of one hand.

The question arises whether all the skin changes are due to syringomyelia or due to pityriasis rubra pilaris, or some allied condition complicated by the syringomyelia. The changes in the hands preceded the syringomyelia by many years; this together with the presence of lesions on the lower limbs where there are no sensory changes is, I think, in favour of it not being due to syringomyelia. Or is this case similar to the case shown by Dr. Wigley in 1929. Hyde (1910) records three similar cases and Stelwagen (1902) records a similar case complicated by generalized pityriasis rubra pilaris. In none of the recorded cases was there any note made of nervous changes except Drummond's case (1939) where he states there were no nerve changes. Hyde in his chapter on ainhum states:

while dead antigens were freely admitted and produced a vigorous response by the manufacture of specific antibodies.

Complete protection against assaulting doses had been produced by him experimentally at University College in Dublin in both guinea-pigs and rabbits with a human type tubercle bacillus solution, all the animals surviving after a subcutaneous dose of both human-type and bovine-type tubercle bacillus. Therapeutic trials in the field in France and in South America in animals were 100% effective. A similar prevention in human beings had been produced by him in practice in Ireland in members of tuberculous families, and a trial producing 100% survival of infants born of tuberculous mothers had been reported by Dr. Eric Pritchard from the Vincent Square Infants' Hospital twenty years ago. He could not understand why the medical and veterinary profession so obstinately refused to have anything to do with this antigen and this demonstratedly successful method.

Mr. John Francis said that it had been estimated several years ago that 40% of dairy cows were tuberculous, and in some areas this was no doubt correct; unfortunately many people had come to believe that 40% of all cattle were tuberculous. As Mr. Ritchie had pointed out this was very far from the truth.

It could not be too strongly emphasized that the main spread of infection occurred in the cowshed and that probably 90% of all cattle were infected by the aerogenous route. There was much less danger of infection when cattle were at pasture.

Efforts to reduce the incidence of the disease by attempting to detect "open cases" would not have been made if there had been a proper understanding of the pathogenesis of the disease. He doubted whether B.C.G. would be of any great assistance in the fight against tuberculosis. M'Fadyean had said that there was really only one method of establishing a tubercle-free herd and that was by the application of the tuberculin test and the elimination of reactors. The method had been applied on an area basis in the U.S.A., Finland, Guernsey and Norway, and in each country the disease had been practically eradicated; good progress had been made in Canada, and even in Denmark where the incidence was high. In Great Britain the Attested Herds Scheme was begun in 1935 and to-day there were now nearly a million cattle in officially tubercle-free herds, but further real progress would probably depend on the establishment of tubercle-free areas.

Salmon, the first Chief of the Bureau of Animal Industry, U.S.A., wrote in 1906: "When public sentiment favours the eradication of tuberculosis in animals the task will not be found an impossible one." The statement was based on a very careful appraisal of the knowledge then available but must have been partly a declaration of faith. The incidence of bovine tuberculosis is high in Great Britain, but to-day there is much evidence that when public opinion is favourable we can confidently begin the process of "stamping-out" bovine tuberculosis.

Pityriasis Rubra Pilaris with Ainhum and Syringomyelia.—K. TATZ, M.R.C.S., L.R.C.P.
(for H. W. BARBER, M.B.).

R. G., aged 51 years. Family and personal history uneventful until 1917 when he developed keratoderma of the palms and soles. About two years later, there developed a scaly rash on his arms and legs which was diagnosed as psoriasis at the time. At about the same time, there developed ainhum-like constrictions and deep painful fissures on his palms and fingers. Six years ago a fissure at the base of his left thumb deepened to such an extent that the thumb fell off; this was not accompanied by any pain. During the next five years the remaining four fingers of the left hand were lost.

In 1944 he had difficulty in moving his left shoulder. X-ray revealed a Charcot joint and a diagnosis of syringomyelia was made.

On examination the patient shows marked keratoderma of the palms and soles. The thumb and distal halves of the fingers of the left hand are missing. All the fingers of the right hand have deep ainhum-like constrictions encircling them. On the forearms, legs and knees there are patchy, scaly psoriasiform areas. On the back of the wrist and fingers there is some follicular hyperkeratosis. The face and scalp are not involved.

Neurological examination reveals typical signs of syringomyelia.

Plasma protein and hippuric acid tests normal.

Blood carotene and blood vitamin A normal.

Biopsy from the back of the hand showed changes compatible with pityriasis rubra pilaris.

Comment.—This is a case of a man who developed keratoderma and fissures with ainhum-like constrictions and a psoriasiform lesion twenty years before the development of syringomyelia with subsequent loss of the fingers of one hand.

The question arises whether all the skin changes are due to syringomyelia or due to pityriasis rubra pilaris, or some allied condition complicated by the syringomyelia. The changes in the hands preceded the syringomyelia by many years; this together with the presence of lesions on the lower limbs where there are no sensory changes is, I think, in favour of it not being due to syringomyelia. Or is this case similar to the case shown by Dr. Wigley in 1929. Hyde (1910) records three similar cases and Stelwagen (1902) records a similar case complicated by generalized pityriasis rubra pilaris. In none of the recorded cases was there any note made of nervous changes except Drummond's case (1939) where he states there were no nerve changes. Hyde in his chapter on ainhum states:

"Some cases of anhidrosis are associated with trophic sensory and vasomotor changes particularly in the limb where the anhidrosis is occurring; the skin of the part may be scaling with wasted muscles, absence of tendon reflexes, and sensibility decreased; keratoderma may be conspicuous." Could not this picture that Hyde describes be similar to this case?

Dr. H. W. Barber: Before I say anything on this case I should like Dr. Leitner, who has been investigating pityriasis rubra pilaris for some time past, to speak to us.

Dr. Z. A. Leitner (*Abstract*): Recently, through the kindness of Dr. Barber, we had the opportunity of studying a family affected by pityriasis rubra pilaris. Two members were under continuous observation for over twenty-two months and in addition three more members of the family with the same disease were investigated (Leitner and Moore, 1946b).

Two forms of pityriasis rubra pilaris—a hereditary and an acquired one—have been repeatedly described (Touraine, 1942). In the course of our investigation we were impressed by the fact that although five of the living six siblings were affected by the disease, two of them were always considered healthy. One of these two supposedly unaffected persons was a man of 45 whose mother was suffering from the disease; his sister had a twenty-five years' history and her son a fifteen years' history of the generalized form of pityriasis rubra pilaris. [These two cases were previously demonstrated to this Section (Leitner, 1945, 1946).] His own son was free from any skin disease, the elder daughter had a very mild form, but the younger one had a more or less generalized pityriasis rubra pilaris, which was first considered as a congenital "eczema". Throughout his life the man himself had palmar hyperkeratosis with typical acuminate papules and projecting cones on the wrists, elbows, knees, and the back of the proximal phalanges, and although he was in the Army for over twenty years, his condition was never diagnosed.

This family history stimulated us to study the hereditary aspects of the disease. A survey of the literature since the beginning of the century yielded 14 more unquestionable instances of familial occurrence of pityriasis rubra pilaris. The data of these 15 families were submitted to Dr. E. B. Ford who agreed that the details of their histories were consistent with the view that pityriasis rubra pilaris is an inherited disease, namely a single autosomal heterozygous condition without sex linkage.

Another aspect investigated was the relationship of pityriasis rubra pilaris to vitamin A metabolism. Since Pettler (1936), several authors have described it as a vitamin A deficiency disease. Some of our cases (the severely affected) had a persistently low vitamin A and carotene level in the blood but others were within the normal range. The degree of clinical involvement in our cases roughly corresponded to the decline of the vitamin A level.

Several other factors also suggested a disturbance of vitamin A metabolism. The rise in the blood vitamin A level after a massive dose of vitamin A usually reaches its maximum after five to eight hours (Leitner and Moore, 1946a). In pityriasis rubra pilaris this was often delayed and to achieve this in one case it took more than two months of continuous dosing. We do not suggest of course that pityriasis rubra pilaris is simply a vitamin A deficiency disease; it may, however, be pertinent to refer in this connexion to rickets resistant to vitamin D treatment first described by Albright (Albright *et al.*, 1937). In his cases normal doses of vitamin D were without any effect, but the disorder of metabolism was corrected by giving continuous enormous doses for a long time (up to 100 times the normal therapeutic dose). After stopping the excessive vitamin D medication florid rickets reappeared within a few weeks' time.

During vitamin A treatment (up to 250,000 i.u. daily for many months) the skin condition improved considerably in all our cases. Perhaps it may be of some importance to mention that every deterioration of the skin condition during vitamin A treatment coincided with a sharp fall in the blood vitamin A level. It cannot yet be stated with certainty whether this coincidence was due to an interference with the absorption of vitamin A, or with its impaired storage or release. As the liver is the main storage organ for vitamin A it is open to speculation whether and how the disturbance in vitamin A

metabolism may be related to this organ. In our cases various liver function tests were carried out and revealed gross impairment of liver function.

Moreover definite signs of endocrine disturbances were also present in our cases indicating a pituitary involvement (cyclic deterioration of the skin condition before menstruation; regular generalized spread all over the body with erythrodermia during pregnancies; cryptorchism).

If we are correct in suggesting that pityriasis rubra pilaris is always an inherited condition, the case of Dr. Barber and Dr. Tatz showing pityriasis rubra pilaris and syringomyelia is of great importance, as syringomyelia is often considered as a congenital disease. Therefore in Dr. Barber's patient two different systems of ectodermal origin appear to be affected, a combination which does not seem to have been described before.

Dr. H. W. Barber: A question has been raised as to whether this man has pityriasis rubra pilaris at all. I did not think there was any doubt of it when I first saw him. On examining him carefully the typical follicular papules can be seen. I agree that the lesions on the legs are like psoriasis, but in my experience when one sees an early case of pityriasis rubra pilaris, it is often impossible to distinguish it clinically from psoriasis. In the former disease, however, an erythrodermia of the palms and soles soon develops, as a rule, and later the characteristic follicular papules. As will be seen from the section submitted in this case, the histological picture is unlike that of psoriasis. The chief interest is the association with syringomyelia and the ainhum-like condition of the fingers and toes. In Dr. Wigley's case the latter was accompanied by keratoderma of the palms and soles, which may, perhaps, have been pityriasis rubra pilaris.

Dr. J. E. M. Wigley: I have not seen the case just mentioned since 1929 in which year I published it, so I have nothing to add.

Dr. F. Parkes Weber: When I was in Paris while Charcot was teaching, this kind of condition—not the dermatological part of it, but the neurological part—was very much talked about, and it was then called "Morvan's disease". After much discussion Morvan's disease was gradually acknowledged to be not a peculiar mild form of leprosy but a clinical type of syringomyelia—the so-called "Morvan type of syringomyelia". The extremely exaggerated knee-jerks and the history of diminished sense of pain and heat in the upper limbs confirm this diagnosis in the present case. I should not be surprised if the callosities were not likewise due to the syringomyelia. Anyhow, in this particular case, the ainhum-like lesions must be part of the syringomyelia. Spontaneous dropping off of distal segments of fingers or toes, as in this man, would in the Middle Ages have branded the patient as a leper.

Lupus Vulgaris treated with Calciferol.—G. B. DOWLING, M.D., E. W. PROSSER THOMAS, M.D., and H. J. WALLACE, M.D.

CASE I.—Mrs. Edith G., aged 73. Lupus of the superficially ulcerative and crusting type began ten years ago on the nose and gradually spread across the cheeks. She has been under the care of the Skin Department at St. Thomas's Hospital during the whole of the period. She was unable to tolerate general light treatment and until October 1943 she was treated by local measures chiefly. Though controlled to some extent, the gradual progress of the disease was not checked by these measures. In October 1943 she was given calciferol, without further local treatment, 50,000 i.u. twice daily, continuing on this dose until July 1944, when she was evacuated to the country. From that time she had no further treatment. She returned to London in October 1945, when as far as could be seen the lupus had disappeared altogether.

CASE II.—Mrs. Alice M., aged 54. She was first seen on January 18, 1945, with extensive lupus of the left side of the face and neck and of the left forearm and hand. The lesions on the forearm and hand were severely ulcerated.

She was given calciferol, 50,000 i.u. three times a day and returned on February 8 with all lesions showing good response. The dose was then reduced to 50,000 i.u. twice daily.

By March 8 the forearm and hand were healed and the lupus on the face and neck was also regressing.

Her state to-day is most satisfactory. All lesions are completely healed and her lupus is clinically cured.

CASE III.—Miss W., aged 35. Patch of lupus on right side of face since the age of 3. Has had most of the usual forms of treatment including Finsen light. Marked activity of the lupus, particularly under the chin, when first seen three months ago. No evidence of tuberculosis elsewhere. Has been treated exclusively with calciferol by mouth, 100,000 i.u. daily, with great improvement.

CASE IV.—Mr. H. E., aged 53. First came under observation twelve months ago with warty lupus of the left buttock. This had first appeared some seven years previously and had been gradually spreading. No evidence of tuberculosis elsewhere. Treatment was begun with one painting of acid nitrate of mercury together with daily administration of 100,000 i.u. calciferol by mouth. Improvement was immediate, out of all proportion to the effects of one application of acid nitrate of mercury. Treatment subsequently was continued with calciferol only, in the same dosage. There has been no evidence of activity for the past two months.

CASE V.—Albert E., aged 34, who for many years before had suffered from tuberculosis of the spine and right hip, developed in 1937 warty lupus of the left thenar eminence. For this he was treated first in 1938 at St. Thomas's Hospital. He then moved elsewhere but returned in June 1945 with an additional warty lupus on the inner aspect of the left foot, which had begun two years previously. Meanwhile, the original lesion had spread serpiginously over the palm and on to the back of the hand between the thumb and forefinger. Under calciferol, 100,000 i.u. daily, the lesions in both areas have completely cleared.

Dr. G. B. Dowling: I do not think any of these cases call for discussion in detail. One of them (Case I) is interesting because she has remained free from lupus though she stopped taking calciferol eighteen months ago. Three of the others (Cases II, IV and V) are remarkable for the rapidity of cure; improvement in each especially in Case II, which was severely ulcerated, took place within a few weeks, and they are all now completely cured. Case III, the lupus of the right cheek and submandibular region, is showing what I consider to be an average response to treatment. She has been taking 100,000 i.u. of calciferol daily for about three months, during which the greater part of the lupus has disappeared though some nodules remain in one area. She will probably require treatment for a further three months, or perhaps rather longer.

These five cases, together with the six who were presented to the Section on November 15, and a considerable number of others which have responded in a similar way to the same treatment, can leave no room for doubt that calciferol in adequate dosage will cure a substantial proportion of cases of lupus. The question that must interest us now is, how does it act? I do not think there is anything to be gained by making guesses; it will be better to try and enlist the interest of those who are best qualified and equipped to set about such a problem. In that case we and others who have charge of clinical material should be able to co-operate in the work of investigation.

Dr. J. E. M. Wigley: May I mention a case which I saw shortly before the previous demonstration? This was a girl aged 3 who, five months after measles, developed multiple disseminated lupus on arms, legs, and face. After the last demonstration (November 15) I put her on calciferol, about 15,000 units twice a day. A fortnight later each of the lupus nodules had become rather indefinite in outline, with a little erythematous halo around it, and one could say optimistically that they all showed signs of disappearing.

Another case was one of a florid, tumid lupus in a woman. Within three weeks of taking 150,000 units of calciferol a day the tumidity had disappeared and the nodules showed signs of flattening.

Lieut.-Colonel F. F. Hellier: It would now appear that we have constructed our wonderful light equipment, our Kromayer, our Finsen-Reyn lamps, merely for the sake of applying a dose of calciferol to the skin, when it could have been given more readily by the mouth. I am particularly interested in the fact that the French discovered the same thing at about the same time. I asked Dr. Dowling if he knew of the French work, but the two were quite independent. The French method, called the method of Charpy, is described in the *Annales de Dermatologie*, for July 1945. The following results were obtained with vitamin D: lupus vulgaris, 20 cases, 20 cures; vegetating tuberculosis, 1 case, 1 cure; lupus erythematosus, 5 cases, no cure, &c. The writer does not give any reference to Charpy's original paper. I feel that this is a fundamental discovery.

Dr. W. J. O'Donovan: Our congratulations are due to Dr. Dowling and his colleagues on all these cases. In a previous discussion on lupus those of us who have devoted years to the subject had to undergo a minor castigation on the ground that we had made a "fetish" of light treatment—an unpleasant word to be published regarding the work of one's colleagues. But Dr. Dowling will find that there is no fetishism of obstruction. There will certainly be none in our lupus clinic at the London Hospital. There is a great institute in Rome which affects to cure lupus by the giving of medicine; it is not run by the profession and it has the highest testimonials from people of eminence outside our profession. A similar claim is made in advertisements from the North of Scotland, I believe, for a certain medical cure of tuberculosis by a lime solution made from calcined bones. I do not wish to advertise it. It may be, as has happened before in medical history, that in fact a serious attack has been made on the disease by those outside our ranks and we are now seeing its adoption and perfecting.

Dr. Franklin Bicknell: There has been very little work done in England on the toxicity of calciferol; it would be of value and easy, now that large doses are being given, to check unconfirmed reports about the premonitory symptoms of poisoning—such as acute tenderness of the back of the head. Presumably some cases of lupus have vascular degeneration, coronary disease or nephritis; in all these conditions calciferol is especially dangerous, so it is important to determine the minimum dose which is effective in curing lupus. It might be possible to give calciferol in an ointment, thereby securing a higher concentration in the lesion and a less high concentration in the arteries.

Kaposi's Idiopathic Sarcoma (With sections).—J. E. M. WIGLEY, M.B.

C. C., female, aged 43, a native of Devonshire. First seen in June 1945 for a painful lesion on the ball of the left foot which had been present about five to six months. The patient stated she had had two previous lesions which had healed with simple local treatment only.

When first seen the lesion was a red, semi-solid angiomatous-looking tumour about the size of a filbert nut which was flush with the surface of the sole of the foot. There was no epidermis over it. A provisional diagnosis of granuloma pyogenicum was made and the tumour removed by diathermy. The removal was not, however, very complete, and the tumour re-formed. In July the whole lesion was excised and sent for section. The surgeon making the excision said that he found the tumour unexpectedly tough.

The section was reported on by the pathologist as a hæmangio-endothelioma and quite definitely not a melanoma.

Subsequently it has been treated with several exposures by penetrating X-rays with only moderate benefit.

When seen on November 22 there was a very definite margined bluish erythema along the inner side of the sole of the foot and also spreading a few inches up the leg. The erythematous area felt slightly indurated. This appearance supported a suspicion that the lesion might be Kaposi's idiopathic sarcoma, which I had begun to consider.

I then examined the section again carefully, and the considerable vascularity and cellular infiltration (rather aggregated around the new vessels) seemed to me to support the clinical suggestion.

Further staining of another section for iron pigment showed a moderate amount of this to be present and seems to me sufficient to justify the diagnosis.

Dr. F. Parkes Weber: There is no Jewish ancestry in this case, and the patient is a woman, not a man. The majority of cases of multiple hæmorrhagic sarcoma in this country—in London at all events—are, and have been for a long time, male cases and of central European Jewish origin. I only mention this to point out that in this case one ought to be particularly careful to confirm the diagnosis considering the patient's sex and ancestry. To my mind, moreover, the case does not look like a genuine one of multiple hæmorrhagic sarcoma. The history of the chronic sore following the growth on the sole suggests to me that the growth was a typical pyogenic telangiectatic granuloma—what the French call "human botryomycoma". I cannot explain the recurrent telangiectatic borderline on one side of the foot, but I suspect that it has something to do with the ulcer on the sole. If that ulcer were healed properly, I think that all the signs of hæmorrhagic sarcoma would disappear.

Dr. Walter Freudenthal: I agree with Dr. Wigley's diagnosis. This form of Kaposi's disease is rare and can easily be missed. A good illustration of it is found in *Jadassohn's Handbuch*, vol. 12/3/2, p. 913.

Dr. J. E. M. Wigley: Recent figures do not appear to support the marked preponderance of Kaposi's sarcoma in the Jewish race, though they do indicate that most of the patients

are of the male sex. The other point is that in this case the original tumour was not soft. The surgeon who tried to remove it remarked to me that it was unusually leathery, which does not suggest to my mind botryomycosis hominis.

Black Hairy Tongue.—C. H. WHITTLE, M.D.

C. R., a man aged 32. Post Office worker. Six months' history. He smokes thirteen cigarettes a day, and gets some post-nasal catarrh. General health good.

The tongue shows long brownish-black hairs on its posterior third, rather more pronounced on the right than on the left.

Microscopy shows the "hairs" to be composed of horny cells, many with nuclei, but showing degenerative changes, in some of which masses of yeast-like bodies are arranged in mosaic form.

Cultures: Monilia in abundance. (Cultures shown.)

Only some of the "hairs" show fungus, but the amount of yeast-like bodies in these is very striking indeed. I had no difficulty in growing the fungus. I should welcome any suggestions as to treatment.

Dr. G. B. Dowling: The mosaic-like arrangement of the spores in the hairs is very striking, and seems to me to suggest strongly that their presence can hardly be purely adventitious.

Dr. W. N. Goldsmith: In 1928 (*Brit. J. Derm.*, 40, 366) I showed at this Section a case of chronic superficial glossitis, with black fur, which had been carefully studied bacteriologically by Dr. R. Ralph. On two occasions he obtained from it in pure culture the two organisms *Nocardia lingualis* and *Cryptococcus lingua pilosa*, which were described. Ralph thought that these two organisms represented a true symbiosis. He had found them together in three other cases of black hairy tongue and had not met them in any other condition. I had another case, however, unaccompanied by glossitis, from which no unusual organisms were cultured. The most effective treatment was massaging the tongue with Monsol ointment.

Lupus Erythematosus in a Girl aged 10.—C. H. WHITTLE, M.D.

J. B., aged 10. A two years' history of an eruption on the nose, cheeks, and scalp, in bat's-wing distribution on the nose and cheeks. The lesions are bluish-red with tough adherent scales and there are several outlying plaques on the face. On the scalp there are two or three areas with similar infiltrated plaques with some hair loss.

The child appears in fair health otherwise, but is liable to sore throats.

The factors which favoured the diagnosis of psoriasis were the good response to sunlight and the presence of undoubted psoriasis in the mother in the usual places, namely knees and elbows. But I am afraid this will prove to be lupus erythematosus. The whole picture with the adherent scales is fairly typical, and I am hoping we shall find a focus. The tonsils are a possible focus, but we shall have to consider the lungs as well.

POSTSCRIPT (9.1.46).—X-ray of chest—no abnormality. Mantoux 1 : 1,000, human and bovine, negative. E.N.T. examination, negative. X-ray of sinuses—left antrum shows slight infective changes.—C. H. W.

P.P.S. (9.3.46).—X-ray of chest negative. Calciferol 30,000 units daily by mouth for two months has been accompanied by some improvement.—C. H. W.

Dr. H. W. Barber: The eruption in this case is clearly lupus erythematosus. Apart from the patches on the face and scalp, she has typical lesions on the lobes of the ears. I think that this form of lupus erythematosus, in which the patches are rather indurated, and in which there is very marked hyperkeratosis with the production of thick adherent scales, is usually of tuberculous origin.

Dr. G. B. Dowling: I understood Dr. Whittle to say that he thought of trying calciferol in this case. I have already treated several cases of lupus erythematosus with calciferol in large doses, including one with an associated tuberculous adenitis, histologically confirmed as tuberculous. In this case as in others calciferol had no effect though the adenitis appeared to be regressing. In a case of sarcoidosis under the care of Dr. Wallace, calciferol has proved equally ineffective.

Dr. W. J. O'Donovan: These are cases in which the distinction between lupus erythematosus and lupus vulgaris appears very inscrutable. I have experience of a very few cases in which over the course of years of observation the diagnosis in very skilled hands has varied at intervals from the one to the other. This may explain unexpected results in treatment.

Dr. W. N. Goldsmith: The face, as a rule, gets worse in the summer, and the fingers better.

Dr. G. B. Dowling: The lesions to which Dr. Goldsmith refers are, I imagine, of the Hutchinson's chilblain lupus type, in which circulatory hypostasis is the predominant factor.

Dr. Whittle: I have never before seen lupus erythematosus in a child so young.

Dr. W. J. O'Donovan: I have seen lupus erythematosus twice in children as young as that, and they died rather speedily. Someone on seeing this case mentioned penicillin. I have three complete cures of lupus erythematosus, of two years' standing or more, with penicillin. I do not think that penicillin will be claimed as a cure for a case with a primary tuberculous focus.

Dr. Barber: Of what did the young children die?

Dr. O'Donovan: In one of the cases the post-mortem showed nothing but cloudy swelling, no tuberculosis and no discoverable focus of sepsis; the other was a private case, and it was not pursued to the end of the story.

Dr. H. W. Barber: In 1943 I described in a letter to the *British Medical Journal* (May 8 (i), 580) a remarkable case of a child, aged 7, who had apparently had lupus erythematosus since infancy. When I saw her, the eruption was very extensive, involving the bat's-wing area of the face, the scalp, neck, ears, back and arms. As in the case under discussion, it was of the indolent hypertrophic type, with thick adherent scales and marked follicular hyperkeratosis. The child had already had one operation for tuberculous cervical adenitis with abscess formation. After the operation the eruption completely disappeared, although she lay out of doors in the sun to which she had formerly always been sensitive. It relapsed, however, with the appearance of tuberculous adenitis around the operation-scar and under the chin, and became more extensive. Another operation was performed, and the eruption improved greatly, but later abdominal tuberculosis supervened when she was under Dr. Mumford's care, and she eventually died of general tuberculosis. If one considers the following points one must, I think, logically conclude that in this case the lupus erythematosus was a toxibuberculide: (1) The rarity of lupus erythematosus in young children, and the unusual severity and extent of the tuberculous adenitis; (2) the complete, but temporary disappearance of the eruption after the first operation on what was at that time presumably the main and primary focus of infection in the glands on the right side of the neck, although the child was freely exposed to sunlight which previously had always provoked an outbreak; (3) the relapse of the eruption associated with involvement of other glands on both sides of the neck and in the submental region; (4) the striking and more lasting improvement in the eruption after the second and more extensive operation; (5) the fact that the eruption, although widespread, was not of the kind usually seen in the disseminate form of the disease, many cases of which have a severe and often fatal streptococcal septicæmia.

Dr. W. N. Goldsmith: I also had a fatal case of lupus erythematosus in a young girl a few years ago. She never had any evidence of tuberculosis. She had had sore throats and occasionally joint symptoms of a rheumatic type, and she died with the usual toxic symptoms and swinging temperature. We did blood cultures repeatedly almost up to the hour of death, and they were all negative. The necropsy showed no trace of tuberculosis or of sepsis anywhere. There were a few little vegetations on the heart valves.

Multiple Keloids following Varicella.—E. W. PROSSER THOMAS, M.D.

Evelyn H., aged 14. She is said to have had a severe attack of chicken-pox six months ago, contracted from her sister, who had an average, mild attack. Many of the lesions became pustular and healed leaving numerous hypertrophic and keloidal scars. These are fairly profusely distributed over the front and sides of the neck and the upper part of the chest, and there are a few scattered elsewhere on the trunk and limbs. The lesions are showing no signs of spontaneous regression, except that they may be paling a little. There was no previous tendency to keloid formation, and there has been none subsequently. I am proposing to treat some of the more conspicuous lesions, e.g. those on the neck and upper part of chest, with Chaoul therapy.

Dr. F. Parkes Weber: This case reminds one of the rather less uncommon development of keloids at the site of vaccination. A long while ago I saw typical post-vaccination

keloids in a girl of about this age, which finally yielded to X-ray treatment. I have seen the patient since, and she has not manifested any special tendency to keloids elsewhere. I presume the X-ray treatment which Dr. Prosser Thomas advocates makes the keloids become pale and gradually causes their atrophy. The natural history of keloids, e.g. those resulting from burns, is that, however long they last, ultimately without special treatment they become pale and gradually atrophy. That ultimate atrophic process, by the way, is part of the natural history of many surgical scars: when old age is reached, sooner or later, they tend to atrophy. Unfortunately this atrophic process in old age is not altogether without its disadvantages, for instance, in regard to the yielding of scars from abdominal and rectal operations.

Dr. W. N. Goldsmith: Thorium X might prove adequate and more convenient than X-rays. It seems strange that thorium X with its slight penetration should have this consequence, but it appears, nevertheless, to do so.

The President: I suggest that the case might be left alone for a year, for I have seen conditions of this kind disappear spontaneously within a year or eighteen months.

Xanthoma of Hands.—CLARA M. WARREN, M.R.C.S., L.R.C.P.

Mrs. S. L., aged 57, has worked for three years trimming rubber. For six months she has noticed oval yellow nodules and yellow staining in the creases of the palms of the hands and of the fingers. There is a cluster of typical xanthomata on each elbow, but none elsewhere.

The patient has not got diabetes, but she comes of a family who are known to be "liverish", who have bilious attacks, and suffer from gall-bladder dyspepsia.

Blood cholesterol 340 mg. % (normal 100-120 mg. %).

Herpes Zoster.—Dr. J. JAWORSKI (introduced by Dr. R. T. BRAIN).

Dr. Jaworski described a method of treating zoster by injections of the patient's own blood. He takes 10 c.c. of blood from a cubital vein in the usual way and injects 5 c.c. under the lesions themselves in several insertions; the other 5 c.c. are injected under the skin near the corresponding spinal ganglions. In most cases one treatment only was given, but in others the injections were repeated once or twice with a day's interval. Dr. Jaworski said he had treated 31 cases of zoster by this method with symptomatic relief and early resolution of the lesions.

No drugs were administered during the treatment.

Section of Surgery

President:—ERNEST FINCH, M.D., M.S., F.R.C.S.

[December 5, 1945]

Sense and Sensibility in the Treatment of Cancer

PRESIDENT'S ADDRESS

By ERNEST FINCH, M.D., M.S., F.R.C.S.

It was almost unnoticed by the medical profession that on March 29, 1939, The Cancer Act was passed by Parliament. This was described in the preamble as: "An Act to make further provision for the treatment of Cancer, to authorize the Minister of Health to lend money to the National Radium Trust, to prohibit certain advertisements relating to Cancer and for purposes connected with the matters aforesaid."

Thus another great scourge of humanity became a statutory disease, having been preceded by tuberculosis and venereal disease. With the exception of cardiovascular diseases, cancer is the most frequent cause of death in this country, the Dominions and United States of America.

In the Bradshaw Lecture given by Sir Alfred Webb-Johnson in November 1940, which was entitled "Pride and Prejudice in the Treatment of Cancer", an attempt was made to steer a course for treatment most advantageous to the patient between the *pride* of the surgeon and the *prejudice* of the radiologist and vice versa.

The treatment of cancer was considered as a radio-surgical problem. It is, however, becoming more than that: as the influence of hormones on malignant growth, both as a causative and therapeutic factor, becomes more understood, endocrinology will play a more and more important part in the treatment. It is perhaps the arbitrary clinical division of cancer into various stages of the disease which has led to the *pride* of the radiologist and the *prejudice* of the surgeon. This clinical division has led to the realization that the treatment of each individual case should be carried out on a consultative basis and assessed by the surgeon, radiotherapist, physician and pathologist with the biochemist and biophysicist in the background.

It is by this and this alone that it can be hoped to achieve what in grateful acknowledgment of Sir Alfred Webb-Johnson's happily chosen title might be called *Sense and Sensibility* in the treatment of cancer.

It is generally admitted that about half the patients suffering from cancer need some form of radiotherapy, which can only be undertaken satisfactorily in special centres, and, in addition, intensive research must be pursued in every aspect of the cancer problem. It was in order to attain this that the Cancer Act was conceived and delivered. It must now be implemented. The responsibility is placed on the local authorities.

keloids in a girl of about this age, which finally yielded to X-ray treatment. I have seen the patient since, and she has not manifested any special tendency to keloids elsewhere. I presume the X-ray treatment which Dr. Prosser Thomas advocates makes the keloids become pale and gradually causes their atrophy. The natural history of keloids, e.g. those resulting from burns, is that, however long they last, ultimately without special treatment they become pale and gradually atrophy. That ultimate atrophic process, by the way, is part of the natural history of many surgical scars: when old age is reached, sooner or later, they tend to atrophy. Unfortunately this atrophic process in old age is not altogether without its disadvantages, for instance, in regard to the yielding of scars from abdominal and rectal operations.

Dr. W. N. Goldsmith: Thorium X might prove adequate and more convenient than X-rays. It seems strange that thorium X with its slight penetration should have this consequence, but it appears, nevertheless, to do so.

The President: I suggest that the case might be left alone for a year, for I have seen conditions of this kind disappear spontaneously within a year or eighteen months.

Xanthoma of Hands.—CLARA M. WARREN, M.R.C.S., L.R.C.P.

Mrs. S. L., aged 57, has worked for three years trimming rubber. For six months she has noticed oval yellow nodules and yellow staining in the creases of the palms of the hands and of the fingers. There is a cluster of typical xanthomata on each elbow, but none elsewhere.

The patient has not got diabetes, but she comes of a family who are known to be "liverish", who have bilious attacks, and suffer from gall-bladder dyspepsia.

Blood cholesterol 340 mg. % (normal 100-120 mg. %).

Herpes Zoster.—Dr. J. JAWORSKI (introduced by Dr. R. T. BRAIN).

Dr. Jaworski described a method of treating zoster by injections of the patient's own blood. He takes 10 c.c. of blood from a cubital vein in the usual way and injects 5 c.c. under the lesions themselves in several insertions; the other 5 c.c. are injected under the skin near the corresponding spinal ganglions. In most cases one treatment only was given, but in others the injections were repeated once or twice with a day's interval. Dr. Jaworski said he had treated 31 cases of zoster by this method with symptomatic relief and early resolution of the lesions.

No drugs were administered during the treatment.

when sent for found to be malignant, yet such a case was kept waiting so that obvious cases of malignant disease might be admitted first.

The treatment of the cancer patient does not end with the successful operation. The Act opens up the whole problem of the treatment of the chronic sick, many of whom are suffering from cancer.

It is necessary that beds be provided for them either in hospitals, hostels, or accommodation in "alms-houses" with adequate nursing and medical attendance.

Also patients in the later stages of the disease should have all the alleviation which modern treatment can afford.

This may mean the surgical relief of pain by operation on nerves, the spinal cord, or amputation.

Centralization of treatment seems to be necessary for the following reasons:

- (1) To secure early diagnosis.
- (2) To secure adequate first treatment. The advantage of early diagnosis is lost if the first treatment is inadequate, so it should be carried out on a consultative basis.
- (3) Radiotherapy apparatus is very expensive and mainly immobile. When such apparatus is installed it must be worked to its fullest capacity. The number of patients must be sufficient to prevent waste.
- (4) The records at a centre can be kept properly and analysed by those skilled in dealing with statistics. Moreover all cases must be recorded, whether treated or not. No one individual has had experience in dealing with a sufficient number of cases to formulate any definite opinions. A retiring surgeon has only dealt with a few hundred at the very outside.
- (5) Discussion and assessment of results at a centre would lead to clinical research quite apart from the purely scientific research of biophysicists and biochemists.
- (6) A staff of expert radiotherapy technicians would be attached to a centre, and would be always increasing their experience by dealing with the special technical difficulties of a whole region.

At the end of the last century radium was discovered and radiotherapy established. In 1929 the National Radium Commission was instituted to control the use of the radium bought as a thankoffering for the recovery of King George V.

The Cancer Act is the logical conclusion of all the research which has taken place into the sensitivity of tissues to radio-activity. The process by which a cancerous change is brought about in tissues must continue to be studied as a necessary prelude to the further means of treatment and prevention of cancer.

Prevention is a public health problem, and will become more so but, as cancer is not notifiable, the incidence of the disease can only be estimated.

The problem for the public health authorities now is not only the prevention but the treatment and also the after-care of the incurables. The education of the community should also be their responsibility. What then should be the "lay-out" for a regional organization? Any scheme must provide for diagnosis, and adequate treatment by any and all means, and it must be such as not only to deal with the primary growth but all subsequent complications.

Radiotherapy will be concentrated in comparatively few centres: regional (university) and co-operating.

The surgery can be done at more scattered centres but under the criticism of the centre and on a consultative basis. Such centres must be adequately equipped and staffed, hence recognition of hospitals rather than surgeons must be the rule. The anomalous position will arise that a surgeon is recognized as competent to deal with cancer cases at one hospital but not at another, such as a cottage or local hospital.

The surgical treatment should be carried out on a consultative basis with the radio-therapist and pathologist.

It may be that a surgical operation is necessary to determine whether a *possible* or *probable* cancer is a *proved* one.

The Cancer Act provides not only for the diagnosis and treatment of the proved case of cancer but also for those patients who are suspected of suffering from it, until the condition is proved innocent. This implies the highest histological skill of the pathologists and in order to establish a diagnosis all the resources of a large polyclinic may be necessary. The importance of a correct diagnosis is not only for the patient but for those administering the financial aspect of the Act.

A regional and co-operating centre should cater for a population of between two and

It is obvious that neither the methods of treatment at present available nor the knowledge already accumulated is being used to the best advantage. The number of deaths from cancer is steadily increasing despite the fact that the "cures" are also increasing.

The main factors contributing to the failure are:

(1) Early diagnosis is not attained. In many instances the general practitioner can make a diagnosis of cancer with great certainty, in other cases it needs the opinion of a specialist reinforced by radiological and pathological examination before a *possible* case of cancer becomes a *probable* one. In other cases a surgical operation may be necessary before a *probable* case becomes a *proved* one. The early symptoms and signs of which the patient complains are common to malignant and innocent conditions. It follows therefore that any clinic which deals with the diagnosis of cancer (which is the declared purpose of the Act) must be equipped to diagnose non-malignant conditions. There should therefore be no *ad hoc* cancer diagnostic clinics in a hospital. The patients should pass through the ordinary out- and in-patient channels.

(2) The first treatment given is not always adequate and this is the all-important treatment. Cancer patients should therefore only receive treatment from physicians, surgeons and specialists of the required degree of training and experience, and if the type of cancer falls within an acknowledged specialty then they should be directed to the appropriate specialist, even if it entails referring them to another centre not necessarily a larger one.

(3) Sufficient use is not made of past experience. This would be rectified if the diagnosis and treatment were under a central (regional) organization with co-operating centres.

The surgery need not be done at the centre but under the criticism of the centre. Treatment should be organized on a consultative plane by regular discussion of cases and results by all concerned. In this way the "Pride and Prejudice" of those interested would be replaced by "Sense and Sensibility" to the advantage of all, especially the patient. The results of treatment could be sifted scientifically and judged dispassionately.

There is no suggestion in the Act of creating "The Cancer Surgeon," but that the treatment should be under an organization which would secure early diagnosis, adequate first treatment, and assessment of results.

How can this be attained? It must be by education both of the community and the medical profession.

Many will disagree with educating the community, thinking that thereby "cancer-dread neurasthenics" will be created. The public must know, however, that the only early sign of a cancer is change in form or function of some organ, and that it is painless in the early stages except in the case of bone. Education of the community has, however, been very successful in the United States and New Zealand. In cancer of the breast the margin between hope and despair is marked by involvement of the axillary glands, not merely clinically but microscopically. On one side of the line there is a 70% to 90% five-year cure, on the other 30% or less.

In 49% of cases the axillary lymph nodes are affected with no clinical evidence of their involvement.

The patient delays asking advice from ignorance, fear, false modesty and gullibility. The Act has provided against the last-mentioned by forbidding the advertisement of "cancer cures".

The medical profession must be educated both in the undergraduate and postgraduate training. Too much stress is laid on the differential diagnosis, and too little on the biopsy results. The arrangement of the cells is the only certain diagnostic test. The present training leads both the undergraduate and postgraduate to believe that a lump in the breast which is not fixed, with no nipple retraction and no palpable axillary glands, is innocent, whereas a biopsy would perhaps prove it to be malignant and thus save valuable time, as adequate early treatment could be given, and instead of 7,000 women dying each year from cancer, the number might be reduced to 1,000.

The general practitioner is the first line of defence, and must be an integral part of the scheme and kept informed of the work at the centre and the results achieved.

Delay in treatment is due to causes other than the delay in diagnosis. There is delay between seeing the practitioner and the surgeon, either from ignorance or fear. The distance from the hospital need no longer be a cause as the Act provides for travelling expenses for the patient and a companion, but the scarcity of beds is one of the main causes for delay. Moreover, a case may be put on the waiting list as being innocent, and

What is the purpose of an abdominal incision? What should it do and what should it not do? An incision should give access to the part to be attacked, and room for the required job to be done. It should be extensible in a direction that will allow for any reasonably probable extension of the scope of the operation. It should interfere as little as possible with the functions of the abdominal wall in the immediate post-operative phase, and it should finally leave it as strong as it was before.

When we demand access to the part to be attacked, we do not mean the most direct access to the whole field of operation, but the best access to its most difficult parts. When we demand extension, we are not asking for an incision that will cover any number of wildly wrong diagnoses, but one that will allow reasonable latitude in scope. A good incision must bring the surgeon to parts that cannot be brought to him, which usually means to roots or pedicles of organs, which again usually means the mid-line, for that is where arteries sprout and ducts empty.

The first essential of an incision in securing access is that it should be placed right. It is equally important that it should be large enough to admit the surgeon's hands and the ordinary tools of his craft. Telemanual technique is indispensable in the various specialties that might be grouped together as orificial surgery, but in the abdomen it is perverted ingenuity. Operating with long instruments and stalked lights has the dramatic appeal of a peepshow, but it can never be as safe or as gentle as work with fingers. One of the truest aphorisms in abdominal surgery is that of Fagge: "Make your incision twice as long as you think it ought to be; then you won't have to enlarge it much." The small incision is the vice of the callow, the cosmetic, and the commercial; it means at best more retraction and trauma than is really necessary, at worst a job poorly done or a necessary job left undone.

The second essential is extensibility. Before opening the abdomen at all, a surgeon must ask himself "What is the matter? What am I proposing to do? What else may I possibly be forced to do?" and he must so plan his incision that he can certainly do the necessary, and can, if need be, extend it to do the contemplated additions. But he must have some idea of what organ he proposes to attack, or at any rate in which compartment of the abdomen he is going to perform. He can extend the standard incisions, the median and paramedian and the lateral oblique or transverse, to a length of twelve inches or more without gross structural damage, but it is seldom right that he should do so. If the diagnosis was right but the operation unexpectedly difficult he needs no more than a moderate extension; if the diagnosis was wrong, he is faced with the difficult alternatives of opening the abdomen like the mouth of a yawning hippopotamus, or closing his original incision and making the right one.

The difficulty arises above all in operations for acute abdominal emergencies. An incision correctly planned for acute appendicitis can be extended to cope with an appendix that is gangrenous and fixed in some unexpected situation; but it cannot be enlarged light-heartedly to deal with a duodenal perforation, an inflamed gall-bladder, a gangrenous pancreas, or a ruptured ectopic gestation. When, after careful investigation and earnest thought, there remains a doubt about the nature of an acute abdominal catastrophe, I believe the surgeon should follow the two simple rules that enable bookmakers to live in Park Lane and spend their week-ends at Brighton: "Bet on probabilities and cut your losses." In the acute abdominal stakes, the form is—appendix odds on favourite, ten to one the field. Therefore when in doubt he should make an appendix incision. In nine cases out of ten he will be right. In the tenth he will establish the diagnosis by fluid that escapes and by gentle exploration with the finger, and can close the first incision and perform the necessary operation through the correct one, having wasted less time and done less damage than if he had started with some compromise applicable to both conditions and suitable to neither.

While the standard incisions I have mentioned can, but very seldom should, be extended to considerable lengths, others are inextensible, being limited either by anatomical confines or by the need to avoid irreparable damage. In the first category are transverse incisions much above the umbilicus which are cramped by the rapidly narrowing epigastric angle, in the second are all vertical incisions near the outer border of the rectus. No surgeon who has seen, as I have, the victim of a full-length incision in the linear semilunaris, the abdominal wall deformed by a large unilateral bulge, the umbilicus in the nipple line, will ever forget the lesson.

The third criterion of a good incision is that it should do the least harm to the abdominal wall itself, to the structures underlying it, and to the patient. In the abdominal

four million. This number is necessary to keep the radiotherapeutic centres economically busy.

There should be an autonomous efficiency and sufficiency in all intermediate and district hospitals with a smoothly working two-way traffic system so that the specialist can go to the periphery and the patients pass from the periphery to the centre.

The technique of radiotherapy will be changing much more rapidly than that of surgery.

Who should do the radium implantation?

Whoever does it must see that:

(1) The help of the radiotherapist and biophysicist is obtained to plan the position and extent of the implants.

(2) The implantation is checked by radiology and the field checked.

(3) The doses are recorded in such a way that the radiotherapist, if subsequent treatment is needed, can successfully and safely adjust the dose.

(4) There is a regular follow-up for at least ten years.

In addition to having a radiotherapeutic department established at the fully equipped regional (university) and co-operating hospitals, there must also be the closest co-operation between them and the district hospitals where the surgery can be done.

There must be consultative centres scattered over the whole region where the general practitioner can send his patients at specified times and where he can attend and join in the consultation of the surgeon, radiotherapist and pathologist. By this means he would not only give his patient confidence and encouragement but also realize the difficulty in many cases of making a diagnosis. His interest would be aroused and this would make him a very important factor in the subsequent follow-up. He should receive a financial sanction for his attendance. The Regional Centre should see that all practitioners in the whole region are kept informed of the results achieved.

The proposals of local authorities cannot be standardized, but broad principles will be suggested to them if asked for. Each scheme must be modified by the density of population, transport facilities and type of industry.

The schemes are to be sent in by the local authorities, but the medical profession must play its part.

In the words from the Talmud:

"The day is short and the work is great. It is not incumbent upon thee to complete the work but thou must not therefore cease from it."

[January 2, 1946]

DISCUSSION ON ABDOMINAL INCISIONS

Major-General Sir Heneage Ogilvie: My task as opener is merely that of the compère, to make some remarks explaining what the show is about, and to keep the audience quiet while the late-comers are getting into their seats. I will use the Socratic method.

What is an abdominal incision? An incision through the abdominal wall. What then is the abdominal wall? It is the whole edifice that bounds the abdominal cavity, and includes the bony framework, the muscular and aponeurotic walls that enclose it in front and at the sides, the diaphragm that roofs it and the pelvic diaphragm that forms its floor. No consideration of the surgical approach to any abdominal viscus is complete unless we think of it in relation to all these walls, and the value of such three-dimensional thinking has been exemplified during the last few weeks in the discovery by Terence Millin of a new surgical approach to the prostate.

The considerable extension of surgical enterprise that has been made possible by advances in anæsthesia, resuscitation and chemotherapy has encouraged the study of alternative approaches, particularly the trans-diaphragmatic approach to organs in the upper part of the abdominal cavity. I suggest, however, that we should be wise to-day to confine our discussion to methods of approach to the organs lying inside and not behind the cœlomic cavity, and to incisions made through the abdominal walls.

What is the purpose of an abdominal incision? What should it do and what should it not do? An incision should give access to the part to be attacked, and room for the required job to be done. It should be extensible in a direction that will allow for any reasonably probable extension of the scope of the operation. It should interfere as little as possible with the functions of the abdominal wall in the immediate post-operative phase, and it should finally leave it as strong as it was before.

When we demand access to the part to be attacked, we do not mean the most direct access to the whole field of operation, but the best access to its most difficult parts. When we demand extension, we are not asking for an incision that will cover any number of wildly wrong diagnoses, but one that will allow reasonable latitude in scope. A good incision must bring the surgeon to parts that cannot be brought to him, which usually means to roots or pedicles of organs, which again usually means the mid-line, for that is where arteries sprout and ducts empty.

The first essential of an incision in securing access is that it should be placed right. It is equally important that it should be large enough to admit the surgeon's hands and the ordinary tools of his craft. Telemanual technique is indispensable in the various specialties that might be grouped together as orificial surgery, but in the abdomen it is perverted ingenuity. Operating with long instruments and stalked lights has the dramatic appeal of a peepshow, but it can never be as safe or as gentle as work with fingers. One of the truest aphorisms in abdominal surgery is that of Fagge: "Make your incision twice as long as you think it ought to be; then you won't have to enlarge it much." The small incision is the vice of the callow, the cosmetic, and the commercial: it means at best more retraction and trauma than is really necessary, at worst a job poorly done or a necessary job left undone.

The second essential is extensibility. Before opening the abdomen at all, a surgeon must ask himself "What is the matter? What am I proposing to do? What else may I possibly be forced to do?" and he must so plan his incision that he can certainly do the necessary, and can, if need be, extend it to do the contemplated additions. But he must have some idea of what organ he proposes to attack, or at any rate in which compartment of the abdomen he is going to perform. He can extend the standard incisions, the median and paramedian and the lateral oblique or transverse, to a length of twelve inches or more without gross structural damage, but it is seldom right that he should do so. If the diagnosis was right but the operation unexpectedly difficult he needs no more than a moderate extension; if the diagnosis was wrong, he is faced with the difficult alternatives of opening the abdomen like the mouth of a yawning hippopotamus, or closing his original incision and making the right one.

The difficulty arises above all in operations for acute abdominal emergencies. An incision correctly planned for acute appendicitis can be extended to cope with an appendix that is gangrenous and fixed in some unexpected situation; but it cannot be enlarged light-heartedly to deal with a duodenal perforation, an inflamed gall-bladder, a gangrenous pancreas, or a ruptured ectopic gestation. When, after careful investigation and earnest thought, there remains a doubt about the nature of an acute abdominal catastrophe, I believe the surgeon should follow the two simple rules that enable bookmakers to live in Park Lane and spend their week-ends at Brighton: "Bet on probabilities and cut your losses." In the acute abdominal stakes, the form is—appendix odds on favourite, ten to one the field. Therefore when in doubt he should make an appendix incision. In nine cases out of ten he will be right. In the tenth he will establish the diagnosis by fluid that escapes and by gentle exploration with the finger, and can close the first incision and perform the necessary operation through the correct one, having wasted less time and done less damage than if he had started with some compromise applicable to both conditions and suitable to neither.

While the standard incisions I have mentioned can, but very seldom should, be extended to considerable lengths, others are inextensible, being limited either by anatomical confines or by the need to avoid irreparable damage. In the first category are transverse incisions much above the umbilicus which are cramped by the rapidly narrowing epigastric angle, in the second are all vertical incisions near the outer border of the rectus. No surgeon who has seen, as I have, the victim of a full-length incision in the linear semilunaris, the abdominal wall deformed by a large unilateral bulge, the umbilicus in the nipple line, will ever forget the lesson.

The third criterion of a good incision is that it should do the least harm to the abdominal wall itself, to the structures underlying it, and to the patient. In the abdominal

wall nerves matter most, for if they are damaged the muscles distal to the point of damage are paralysed; muscles come next in importance, for they heal by fibrous tissue only, but if the scar is strong and narrow no harm ensues; fibrous and aponeurotic structures matter least, for they repair after division with their own tissue; blood-vessels should be considered, but the arterial anastomosis in the abdominal wall is so free that no proposed incision is likely to be excluded on grounds of the danger of ischæmia. Not only must the structures divided by the knife be taken into account, but the line in which they are divided; when they are cut across their line of strain, stitches pull out and weak areas tend to appear, but when they are cut in that line the edges of the gap tend to be self-supporting, and a few sutures only are needed to approximate them in the immediate post-operative phase.

While avoiding damage to the structures of the abdominal wall itself, a good incision should also take into account the possibility of adhesions to its deeper surface. Adhesions will happen in the best regulated incisions, but whether they are harmful will depend on where they are and what they fix. Fixation of the already fixed matters little; it is only fixation of the mobile that causes symptoms. Adhesions to the colon or liver, that is in the upper or lateral parts of the abdominal cavity, are relatively harmless; those involving the small intestine, that is in the umbilical and hypogastric regions, may be harmful and even dangerous.

Lastly, a good incision must spare the patient. So far I have spoken of the abdominal wall as the first obstacle to surgical enterprise. I must remind you that it is also a prime factor in the maintenance of life and the preservation of health. It maintains abdominal pressure and holds the viscera against the constant efforts of gravity to crowd them into the pelvis. In respiration, it is the recoil mechanism of the diaphragm. In the circulation, it is the counterpart on the venous side of the heart on the arterial side.

Of the abdominal muscles, the recti serve locomotion. They are the flexors of the trunk and opponents of the erector spinæ. Their action is chiefly phasic, and in certain actions, such as rowing, they may be completely relaxed though the abdominal pressure at the time is very high. The rectus sheath has a spatial but not a functional relationship to the muscle. It is the common tendon of the lateral muscles, and is inserted into the linea alba. The strain on it, and the direction of its fibres are almost entirely transverse.

The lateral muscles can act individually in phasic contractions as benders and rotators of the trunk, but as a group their action is postural. They are the maintainers of abdominal pressure and the emptiers of the lungs.

To sum up, the stresses on the abdominal wall are transverse and are constant. The recti are out of action when a patient lies or sits with the trunk and hips flexed, but the lateral muscles maintain their tone and continue their rhythmic contractions while life lasts. Transverse incisions through the lateral parts of the abdominal wall and through the rectus sheath have therefore the support of physiological reasoning, in that they maintain the functions of circulation and respiration unimpaired from the beginning, and of technical requirements in that they are in the line of strain, and after closure they depend little on sutures for their security. Incisions across the rectus muscle have no such sound support, and base their appeal chiefly on giving wide access.

Thus the incisions to which we can give unqualified support are few. Foremost among them are the lateral incisions. These may be strictly transverse or they may be oblique in the line of the nerves, but they should not slope upwards and inwards. They may go as far back as the erector spinæ and as far forward into the rectus sheath as the rectus muscle can be retracted, but they should not cut across it. These incisions increase steadily in popularity. They give excellent access to any structure lying on the same side between the pyloric plane and the pubis. They heal up without incident, they never seem to give way, and they allow unimpeded respiration and coughing from the beginning. Within the last two years they have, in my practice, ousted the lower median and paramedian incisions for all purposes except the most straightforward appendicectomy. For this I still use, as always, the gridiron, which is, after all, the baby of the lateral family.

There are also the vertical incisions in the linea alba or through one or other rectus sheath. They can be any length that the abdominal wall allows, but they should not stray more than an inch from the mid-line. I am tending, like other surgeons of my acquaintance, to abandon incisions that involve the separation of planes and the retraction of layers. Their separated planes leave potential spaces where fluid

may collect and infection may appear and, so far from giving added safety, they are more prone to wound disruption than simpler methods. For this and other reasons I am becoming increasingly attached to the mid-line incision. I used to deplore its limited length, but since I learned from Victor Bonney that the umbilicus is no prohibited area I have cut through that central ornament freely from above or below. The mid-line approach offers the best access to the attics and cellars of the abdomen, and the felted structure of the linea alba gives a better hold for stitches than the anterior and posterior rectus sheaths combined, structures which are all warp and no woof. Since no muscle is cut post-operative pain and therefore respiratory inhibition is less than in the paramedian incisions.

The right and left paramedian rectus-retracting incisions remain standard doors to the abdominal cavity, and very good they are provided they are not used in septic conditions. For these, for an operation on a gangrenous gall-bladder or a gangrenous appendix, I should prefer to cut through rectus sheath and muscle in the same plane.

With regard to closure, I would prefer to seek principles rather than to discuss details. Repair is a function of the tissues, and stitches do no more than bring them into apposition and hold them there while the gap is bridged by living fibroblasts. When there is constant strain on the suture line, stitches, whatever their material, cut through by pressure necrosis and separation follows. Further, there is no "key" layer in abdominal closure; all must be taken into account, and all must heal equally. A chink in the peritoneal suture may lead to wound disruption, or to hernia later. A hæmatoma or a dead space in the rectus sheath may breed an infection that will reach the peritoneum with even greater ease than a peritonitis infects the layers of the incision.

The peritoneum and posterior rectus sheath are usually closed together. Here we seek to provide not only strength, but an unbroken deep surface to which nothing can adhere. A plain over-and-over stitch leads inevitably to inversion and adhesion. In most incisions a continuous everting mattress suture of fine catgut is the best way of closure. In a gridiron incision, the peritoneal opening can be closed by a purse-string, leaving only a dimple on its deep surface.

The muscle layers must be sutured in as many strata as have been cut. In the lateral incisions therefore three layers of suture are required, and, since there is no tension, they may be continuous without reinforcement. In median and paramedian incisions one layer only is closed above the peritoneum, and that a layer divided at right angles to the stresses it-undergoes. Here an unsupported continuous suture is not enough, it should be interrupted, or, if continuous, should be supported by mattress sutures of unabsorbable material. Accurate suture of the skin involves also obliteration of all dead space in the fatty layer. Where deep tension sutures are used they serve this purpose in addition to their primary one; otherwise a series of deep skin sutures must be placed. The actual epithelial apposition is served by Michel's clips or fine edge-to-edge stitches which are removed in three or four days.

I have tried to define a good incision and will now attempt to discuss the poor incisions. There are a number of incisions which are permissible, but which most of us have tried and found wanting. Chief among these are the trans-rectus incisions. The transverse incision across both recti has much to recommend it. It gives the most wonderful access to the upper abdomen. It is physiologically sound, or at any rate based on sound theory, and had therefore an irresistible appeal to every surgeon fresh from the Primary. Its disadvantage is that, the rectus muscle being unsuturable, a space always remains where its fibres are cut, harmless if it repairs by first intention, disastrous if further hæmorrhage or infection ensue. It was a favourite with the magnificent young men who did the forward surgery in the Desert. But the surgeons in South Africa wrote, more in sorrow than in anger: "For God's sake stop your boys from cutting across the rectus; we have never seen such herniæ before, nor in our wildest nightmares have we dreamed them possible."

The Kocher leads us to more acute controversy. It cuts one nerve at most, it does not bleed much, and it usually heals well. I was brought up on it, and I have never admitted abandoning it. I used it last week, and doubt if I shall ever use it again. It gives marvellous access to the fundus of the gall-bladder, which does not interest me, and very poor exposure of that deep Clapham Junction at the liver hilum where ducts join and arteries branch, a region I never approach without anxiety or leave without thankfulness.

wall nerves matter most, for if they are damaged the muscles distal to the point of damage are paralysed; muscles come next in importance, for they heal by fibrous tissue only, but if the scar is strong and narrow no harm ensues; fibrous and aponeurotic structures matter least, for they repair after division with their own tissue; blood-vessels should be considered, but the arterial anastomosis in the abdominal wall is so free that no proposed incision is likely to be excluded on grounds of the danger of ischæmia. Not only must the structures divided by the knife be taken into account, but the line in which they are divided; when they are cut across their line of strain, stitches pull out and weak areas tend to appear, but when they are cut in that line the edges of the gap tend to be self-supporting, and a few sutures only are needed to approximate them in the immediate post-operative phase.

While avoiding damage to the structures of the abdominal wall itself, a good incision should also take into account the possibility of adhesions to its deeper surface. Adhesions will happen in the best regulated incisions, but whether they are harmful will depend on where they are and what they fix. Fixation of the already fixed matters little; it is only fixation of the mobile that causes symptoms. Adhesions to the colon or liver, that is in the upper or lateral parts of the abdominal cavity, are relatively harmless; those involving the small intestine, that is in the umbilical and hypogastric regions, may be harmful and even dangerous.

Lastly, a good incision must spare the patient. So far I have spoken of the abdominal wall as the first obstacle to surgical enterprise. I must remind you that it is also a prime factor in the maintenance of life and the preservation of health. It maintains abdominal pressure and holds the viscera against the constant efforts of gravity to crowd them into the pelvis. In respiration, it is the recoil mechanism of the diaphragm. In the circulation, it is the counterpart on the venous side of the heart on the arterial side.

Of the abdominal muscles, the recti serve locomotion. They are the flexors of the trunk and opponents of the erector spinæ. Their action is chiefly phasic, and in certain actions, such as rowing, they may be completely relaxed though the abdominal pressure at the time is very high. The rectus sheath has a spatial but not a functional relationship to the muscle. It is the common tendon of the lateral muscles, and is inserted into the linea alba. The strain on it, and the direction of its fibres are almost entirely transverse.

The lateral muscles can act individually in phasic contractions as benders and rotators of the trunk, but as a group their action is postural. They are the maintainers of abdominal pressure and the emptiers of the lungs.

To sum up, the stresses on the abdominal wall are transverse and are constant. The recti are out of action when a patient lies or sits with the trunk and hips flexed, but the lateral muscles maintain their tone and continue their rhythmic contractions while life lasts. Transverse incisions through the lateral parts of the abdominal wall and through the rectus sheath have therefore the support of physiological reasoning, in that they maintain the functions of circulation and respiration unimpaired from the beginning, and of technical requirements in that they are in the line of strain, and after closure they depend little on sutures for their security. Incisions across the rectus muscle have no such sound support, and base their appeal chiefly on giving wide access.

Thus the incisions to which we can give unqualified support are few. Foremost among them are the lateral incisions. These may be strictly transverse or they may be oblique in the line of the nerves, but they should not slope upwards and inwards. They may go as far back as the erector spinæ and as far forward into the rectus sheath as the rectus muscle can be retracted, but they should not cut across it. These incisions increase steadily in popularity. They give excellent access to any structure lying on the same side between the pyloric plane and the pubis. They heal up without incident, they never seem to give way, and they allow unimpeded respiration and coughing from the beginning. Within the last two years they have, in my practice, ousted the lower median and paramedian incisions for all purposes except the most straightforward appendicectomy. For this I still use, as always, the gridiron, which is, after all, the baby of the lateral family.

There are also the vertical incisions in the linea alba or through one or other rectus sheath. They can be any length that the abdominal wall allows, but they should not stray more than an inch from the mid-line. I am tending, like other surgeons of my acquaintance, to abandon incisions that involve the separation of planes and the retraction of layers. Their separated planes leave potential spaces where fluid

recommended by Pfannenstiel, may be justified at times, but only rarely, and when the diagnosis is beyond doubt. They are, of course, perfectly adequate for the removal of a normal appendix, but we do not spend our lives removing normal appendices.

For an incision to be sightly it should be made with a sharp knife, the skin should be divided at right angles and hæmostasis should be perfect. My only other contribution to a good cosmetic result, is that I excise the scar of a previous operation, if I am opening the abdomen for a second time, so that the patient is left with a single scar.

My standard incision is the paramedian, either right or left, upper or lower abdominal, according to the structure which is to be operated on. In operations on the stomach I prefer the right paramedian for duodenal ulcer, and the left paramedian for gastric ulcer or carcinoma. In resections for duodenal ulcer it is the duodenal end of the stomach which is most likely to be difficult, and a right paramedian incision gives the most direct access to it. In gastric ulcer and carcinoma, a high resection may be called for, and the cardiac end of the stomach can be approached most directly through a left paramedian incision. Paramedian incisions are perfectly satisfactory for colon work, as it must be remembered that when the colon has been mobilized, its mesentery is attached to the central part of the posterior abdominal wall.

For operations for acute appendicitis, I employ a Battle's incision. It has the advantage of not exposing a great deal of the abdomen in the presence of a septic lesion, but its drawback is that it cannot be extended at all easily if the diagnosis is found to be at fault. Should this happen, I close the peritoneum, allow the rectus to fall back into position, extend the skin and anterior rectus sheath part of the incision, and then displace the muscle outwards.

For operations on the biliary tract I use a right paramedian incision in the large majority of cases, and in occasional cases only, particularly in fat subjects, I use a subcostal incision.

In closing my abdominal incisions, I close the peritoneum with a continuous catgut stitch, and if it is at all thin, and seems likely to tear, I pick up a small piece of the under side of the rectus muscle in each stitch to reinforce it. The rectus muscle is allowed to fall back into position; if it is thin and sometimes in the lower part if the incision extends down to the pubes, I fix its inner edge by one or two interrupted sutures to the linea alba. The anterior rectus sheath is closed by interrupted sutures, tension sutures are put through skin, subcutaneous fat and the anterior sheath of the rectus, and finally, the skin edges are approximated with Michel's clips. If a drainage tube has been employed, I put a separate stitch next to it in each layer, so that if it should happen to be eroded no harm results.

I use catgut throughout, except for the tension sutures.

Finally, I put on a sealed dressing, largely to prevent the nursing staff from looking at it. There is no reason for dressing a wound until the clips are removed on the fifth day.

I know that the closure of abdominal incisions is not a matter of the greatest interest to surgeons generally; only too frequently do we leave this part of the operation to our assistants, and even students tend to be bored, and to take no interest in this part of the proceedings. In all circumstances I consider that we should at least close the peritoneum, in view of the importance of this step in its relation to incisional hernia. In addition, if we hand over to our assistants before this is done, there is sure to be a misunderstanding sooner or later, and a swab will be left behind.

I have not attempted to enumerate the various incisions which can be used, but merely to lay down certain principles, and to tell you what I do myself. Surgeons are bound to have individual preferences, as to the way in which they open and close the abdomen.

Professor John Beattie: *Metabolic Changes after Injury.*—Injuries of any kind, whether deliberate or accidental, are followed by a series of changes at the site of injury which are already well known. Less well known, however, are the profound general changes in bodily metabolism which are the inevitable consequences of trauma. Cuthbertson

There are incisions which have the common factor that they divide no muscle but give a wide opening in the mid-line by dividing the anterior and posterior rectus sheath at right angles to each other. These are Pfannenstiel's infra-umbilical and Sloane's supra-umbilical incisions. They are ingenious, and to those who like ingenuity they will make a constant appeal, but it cannot be claimed that they have established any secure footing in abdominal practice.

There are bad incisions too. One that fails on every count, access, extensibility, security, is the Battle. I hope the day will come when the reasons for removing a doctor from the register will move on from the abject A's, alcohol, adultery and advertising, to the baleful B's, Battle and Bassini. A patient who loses his wife can find another; one who seeks treatment in response to an advertisement, either a frank one or a discreet paragraph in the evening press, gets the kind of doctor he asks for; but the man whose abdominal wall or inguinal canal is ruined is indeed betrayed by the profession to which he has entrusted his health.

Mr. Digby Chamberlain: An abdominal incision should: (1) Give adequate access to the structure to be operated on; (2) Leave a firm scar when it has healed; (3) Be as little unsightly as possible.

The satisfactory making and closing of abdominal incisions is as dependent on the anaesthetist as on the surgeon. With good muscular relaxation, it is possible to explore the abdomen in comfort, and to carry out the necessary operative procedures through an incision which might be quite inadequate with a less favourable anaesthetic. My own preference is for an intratracheal intubation, and I find that with it, I get a slack abdominal wall, and that I practically never use a retractor, except the hand of my assistant.

Abdominal relaxation is of further importance in the incidence of incisional hernia. King (1935, *Brit. J. Surg.*, 23, 35) is of the opinion that these hernias and burst abdomens start by the cutting out of the peritoneal stitch, or the escape of a tag of omentum between the stitches during the closure of the abdominal wall. We all know how prone this is to occur in a patient who is straining under the anaesthetic.

It is a fundamental rule that the incision should be adequate; much harm can be done by using too small an incision. Blind manipulations cover a multiple of sins, and it may only be the patient, or the pathologist, at a later stage, who is conscious of their extent.

I remember being very impressed on reading "Fifty Years a Surgeon", by Morris's description of the removal of a stone from the ureter! A small gridiron incision is made in the iliac fossa, through which a finger is put, and the stone is felt on the posterior abdominal wall. With the finger in this position, the patient is rolled over, and a stab wound is made in the back, on to the tip of the finger. The point of the knife in this way opens the ureter and grates on the stone. A pair of forceps is inserted along the knife, and made to grasp the stone, which is then removed. To paraphrase M^{re}chal Bosquet: "It is magnificent, but it is not surgery."

A rapid and systematic examination of the abdominal contents should always be made, before dealing with the organ to which the symptoms have pointed pre-operatively.

The second consideration, that the scar should be firm, depends very largely on the suturing of the peritoneum, and is bound up closely with the anaesthetic. I believe this to be more important than post-operative cough or distension, or the too early return to heavy work. These factors may play a part, but they are much more likely to do so if there is a peritoneal defect, however small it may be.

There are certain factors to which we all subscribe. Nerves should be avoided, and it should not be forgotten that splitting the rectus muscle is bound to denervate its inner part. Blood-vessels are not of great importance, they are so numerous that we cannot seriously interfere with the blood supply of any part of the abdominal wall by dividing them, but bleeding must be controlled as hæmatoma formation favours infection. Muscles are better displaced than divided, although I know that many surgeons habitually, and deliberately, divide certain of the muscles of the abdominal wall.

The third consideration, the cosmetic result, is of small importance. A small incision, lying in a crease and following Langer's lines or a transverse suprapubic incision as

contain all the other essential amino-acids. The success of high protein—high caloric diets in injured Servicemen in speeding up convalescence has been confirmed by many groups of workers in different operational theatres during the last eighteen months of the war.

So far only the effects of injury on otherwise healthy subjects have been considered. The responses to injury in the debilitated human subject are quite different. It matters little whether the cause of debility is tuberculosis, severe infection, high protein loss due to burns, cancer, or starvation. If the debility is extreme, accidental or deliberate wounds do not heal or if they do heal the scars are weak. In Holland before the liberation, surgical work was almost suspended because of the tendency for abdominal and other wounds to remain unhealed often for weeks. Metabolic studies of debilitated individuals who have sustained an injury reveal that there is no increase in the nitrogen excretion during the period when it would be expected were the patient well nourished. Moreover, protein given in any form by any route does not lead to an immediate rise in nitrogen excretion. It would appear that protein is held tenaciously, perhaps as a protective response, to conserve protein needed for the continued existence of the individual. If treatment with high protein—high caloric diets is persisted in, sooner or later the nitrogen output will rise and coincident with this rise normal healing will commence.

Within the past few years it has been discovered that the urine from injured animals and human subjects contains a much increased content of the adrenal cortical hormone—cortin. This hormone has the property of inhibiting the synthesis of protein from amino-acids. Consequently large quantities of these substances are de-aminized in the liver and some non-nitrogenous moieties built up into glycogen. If protein is being destroyed after injury in order to furnish quantities of some essential component, large masses of amino-acids which are not required are set free. If methionine were in fact the essential substance required by the organism, 97% of the protein molecule destroyed would be available for the de-amination and utilization as fuel. The presence of excess cortin enables this utilization to be effected. In debilitated patients cortin excretion is not increased.

Another hormone—testosterone—has precisely the opposite action to cortin. It accelerates the synthesis of protein from amino-acids and hence promotes storage of protein. Protein, however, cannot be synthesized unless adequate quantities of each of the amino-acids needed to build the protein molecule are available. Under conditions of injury the output of testosterone in the urine is diminished. Cuthbertson, Shaw and Young (1941) observed that injections of crude extract of the anterior pituitary gland of the ox into rats which had had simple fractures of the femur prevented the loss in body-weight and excessive loss of nitrogen in the urine which followed such injuries in control animals. Although protein was conserved within the body as the result of such treatment they noted in another series of experiments that skin wounds did not heal more rapidly when the same pituitary extract was administered. Such observations may lend indirect support to the view that protein destruction after injury is effected to set free from the protein molecule some component which is necessary for repair.

The relation between the increased excretion of nitrogen and the excessive production of cortin is by no means clear. In the intact animal, injections of cortin will not induce a negative nitrogen balance. It seems probable, therefore, that the increased nitrogen excretion is caused by the increased cortin production.

It is obvious that the treatment of injury must include some attempt to minimize the effects of the high protein catabolism in the first phase and to produce as high a positive nitrogen balance as possible in the third phase. The aim of this treatment should be to provide a protein intake of not less than 2 grammes per kilogramme of body-weight per day in an otherwise normal human adult, and if possible 2.5 grammes. If the intake can be increased above this level the convalescent period will be noticeably shortened.

The protein intake can be increased by four methods: (a) A high protein diet where the major part (over 75%) of the protein is available from milk, eggs, cheese or meat; (b) the oral use of hydrolysed proteins such as casein or meat; (c) the intravenous infusion of solutions of protein hydrolysates; (d) the intravenous administration of human plasma.

The high protein diet of around 150 grammes of protein per day has also a high caloric value. The total calories should be not less than 2,000, but the ideal is about 3,000 for a

(1929) observed in animals who had simple fractures of the long bones that the amount of nitrogen excreted each day in the urine increased considerably during the two weeks immediately after the injury had been inflicted. Since 1929, and especially during the war years, it has been shown, both in healthy animals and in well-nourished human subjects, that an increased nitrogen excretion is a constant finding after injury. Stevenson and his colleagues (1945) made detailed studies of human subjects suffering from moderately severe injuries and came to the conclusion that the disturbances in nitrogen metabolism fall into three phases. For a period of two to three weeks after the injury the amount of nitrogen excreted far exceeds that taken into the body in food. The nitrogen balance is thus negative. Immediately following this negative phase there is a period of about a week when the nitrogen intake and output just about balance. The third phase, lasting five or more weeks, is characterized by a positive nitrogen balance, i.e. the intake exceeds the output. At the end of this third phase, input and output are approximately equal and the patient may be said to be "recovered".

It is obvious that the excess nitrogen excreted during the first phase of negative nitrogen balance must come from the destruction of body proteins. Normal adults confined to bed and not suffering from any injury or infection lose weight and show an increase in nitrogen excretion. This increased protein destruction can be called the atrophy of disuse. The magnitude of this destruction is, however, not sufficient to account for the amount of nitrogen which appears in the urine after injury. The protein destruction in such cases is an active breaking down of body protein not due to atrophy of disuse.

Nothing is known about the mechanisms which bring about this active protein breakdown (catabolism). They may be presumed to be of a hormonal nature and are set in motion by substances liberated from the damaged tissues. No precise data exist which confirm or contradict such a hypothesis. Various ideas exist as to the meaning of this profound disturbance of protein (nitrogen) metabolism, but here again precise data are lacking. It has been suggested that the breakdown provides the body with a readily available source of energy. If this were so then a diet of a high energy value ought to avert or minimize the amount of body protein destroyed. Trials of such treatments have shown clearly that while some patients show a diminution in the nitrogen excreted the results as a whole do not support the hypothesis. It has been suggested that protein is broken down in order to provide adequate quantities of some protein component which is necessary for the processes of repair. This latter idea has had some experimental support.

Rose and his co-workers (1942) over a period of many years have demonstrated that growth in rats can be halted or retarded when one or more of a number of so-called "essential amino-acids" are absent from the diet. These amino-acids are "essential" in that the animal body cannot synthesize them and that they must be present in the proteins of the food or as the pure substances in artificial diets. Croft and Peters (1945) showed that after experimental thermal burns in rats the negative nitrogen balance which ensues could be diminished markedly when one of the essential amino-acids—methionine—was added to the animals' diet. The deduction from these experiments would thus appear to be that protein is destroyed to secure adequate supplies of methionine. The great protein destruction may be explained by the fact that methionine forms only around 3% of the body proteins. As the protein content of body tissues is about 20% by weight, it would be necessary for 500 grammes of tissue to provide 100 grammes of protein and 3 grammes of methionine. It must, however, be realized that the average human adult weighing around 65 kg. needs about 2 grammes of methionine per day, and if animal experiments are a true guide, growing human subjects would require much more in proportion to their body-weight. It would therefore not be unreasonable to suppose that when the repair processes are active, and they are only but a special type of growth, the methionine requirements of the body may be doubled. Experiments on human subjects suffering from moderately severe injuries have shown that there is a diminution in the rate of protein destruction when doses of 3 to 5 grammes of methionine are given each day during the phase of protein catabolism. Much more accurate and detailed work is needed before it can be stated dogmatically that the excessive protein destruction after injury is an attempt on the part of the organism to meet an increased demand for methionine. When a high protein intake—over 150 grammes per day—is given to patients suffering from severe injuries, the negative nitrogen balance can be diminished until it either becomes negligible or is converted into a positive one. Although the components of such a high protein diet are rich in methionine, they also

Penicillin in Ophthalmology. (*Abstract*)

By Professor ARNOLD SORSBY, F.R.C.S.

(1) *Ocular Pharmacology of Penicillin*

A. Tolerance: In the form of drops concentrations up to 2,500 units per c.c. are well tolerated. In ointment form the difficulty so far has been the lack of an adequate base which would not decompose the penicillin and allow of ready absorption. Subconjunctival injections of 600 units in 0.5 c.c. of water are well tolerated and can be repeated daily. Injections into the anterior chamber of quantities of 100 to 200 units are justifiable. Injections into the vitreous are not well borne; the upper limit is probably not much more than 100-200 units. An allergic reaction taking the form of massive swelling of the lids on instilling one drop of penicillin (2,500 units per c.c.) has been observed.

B. Concentration: (1) *Systemic injection*.—On the injection of clinical doses in the rabbit and dog, no penicillin can be recovered from the interior of the eye. These observations have been partly confirmed in man.

(2) *Local applications*.—(a) Drops: No penicillin can be recovered from the interior of the eye in both the experimental animal and in man on the instillation of drops.

(b) Corneal baths and ionization produce a considerable concentration in the aqueous and other ocular tissues of the experimental animal.

(c) The possibilities with lamellæ have not yet been adequately explored.

(d) Ointment bases which damage the corneal epithelium allow a considerable concentration in the aqueous.

(e) Subconjunctival injections of 2,500 units in the experimental animal and 4,000 units in man also allow a fairly high concentration in the aqueous. This is probably not maintained for any length of time.

(f) Injection into the anterior chamber: 500 units injected into the anterior chamber of the rabbit showed the highest level of concentration one hundred and five minutes after injection. Excretion is probably rapid.

(g) Injection into the vitreous: An injection of 5,000 units in man still showed an appreciable amount of penicillin after forty-eight hours.

(h) Modifying factors.

Wetting agents of the aerosol group do not materially affect absorption through the cornea. Absorption is more ready after corneal bath, ionization, and in corneal abrasions and ulcers.

healthy adult. To obtain such an intake, supplementary milk drinks of the type used by Stevenson (1945) are ideal. Protein hydrolysates by mouth suffer from the disadvantage that they are unpalatable unless great trouble is taken to flavour them. They have many advantages. If given by gavage, the fluid and caloric needs of the patient can be met easily at the same time. Moreover, if given over a period of many hours at a slow rate—5 c.c. of 5% solution of the hydrolysate per minute—they are rapidly absorbed and leave no residue. In some patients they are not easily tolerated by the intestinal mucosa and may produce a diarrhoea. Reduction of the total intake by lessening the rate of input often leads to a successful administration. The administration of protein hydrolysates by vein has proved of considerable value in the treatment of the debilitated patient and of patients in whom it is considered unwise to give anything by mouth for a period of days. Suitable preparations, however, are not readily available and some time must pass before any extensive trial of them can be made in civil practice in this country.

In the otherwise normal patient, all the above treatments lead to an increase in the nitrogen output, but it is found that the nitrogen balance is rendered less negative. In debilitated patients, this rise in nitrogen output is not observed. It may be presumed therefore that the nitrogen is conserved as protein. When plasma is given to both normal and debilitated patients the nitrogen output is *not* increased. This whole protein (plasma protein) apparently enters rapidly into the cellular elements and does not participate in the metabolic activities induced by the injury. In cases of injury, except where plasma is used to assist in the restoration of the plasma volume or to replace the loss of whole protein as in burns, plasma infusion is not a method to be used in place of the three methods already mentioned. If it be true that the increased protein metabolism in injury provides adequate supplies of some protein constituent necessary for the repair process, then whole plasma protein by vein must be broken down before it can supply this constituent. The most economical way to provide this hypothetical constituent would seem to be by a proper diet and failing that by hydrolysed proteins given by mouth or by vein.

The treatment of the debilitated patient is identical with that of the otherwise normal, except that the intake must be made as high as possible if convalescence is to be rapid and healing sound. Successful treatment is followed after a few days or a week by a gradual rise in nitrogen output. Maintenance of a high nitrogen input until healing is well advanced is essential.

The use of vitamins to accelerate healing has been investigated by numerous observers. Vitamin C (ascorbic acid) is one vitamin which seems to be concerned intimately with the repair process. After injury this substance disappears from the urine and cannot be made to reappear even when large quantities of it are administered. It is known that it is concerned in some way with the formation of cortin, and it is also essential for the production of collagen so necessary for the development of strong scar tissue. The level of intake of ascorbic acid should be at least twice the accepted optimum for adults.

It has not been possible in this paper to mention the many groups of workers who have contributed so much to our understanding of one aspect of the effects of injury. The various conferences in New York on wound healing convened under the auspices of the Macy Foundation have been a great stimulus to those of us in this country who have investigated some of the problems of wound healing. Although much has become known since 1939, we are still a long way from understanding the fundamental mechanisms involved in the healing of even a clean surgical wound.

Mr. L. H. Savin asked how frequently an allergic response was seen. He added that he was not wholly convinced about the trachoma case, because he had seen rapid improvement occur in trachoma under ordinary methods. Was any other treatment adopted at the same time as the penicillin?

Mr. R. Lindsay Rea had had a case of a man discharged from the Army with multiple thromboses throughout his body—arms, legs and chest—and on examination he found a central scotoma had just developed in one eye. The dental radiographs showed the teeth to be extremely infected and Dr. Bodman suggested that during the removal of the teeth he should have at the same time heparin and penicillin drip given intramuscularly to prevent a further thrombosis as the clotting time of the blood was so low—with the result that no untoward happening took place and the scotoma was reducing in size.

He had always felt some trepidation in an eye case when teeth had to be removed wholesale and it was well to know that penicillin could be used as a drip during the time of and immediately after the dental operation.

Professor Sorsby said he had been asked whether ionization had been tried in septic inflammation of the eye. In a case—reported by Dunnington and v. Sallmann—of post-operative infection of the eye which was treated by ionization together with systemic administration, the condition cleared up.

No one could speak with certainty as to the effective concentration of penicillin, as there was a difference in the susceptibility of different organisms. What was an effective concentration in one case would not be the effective concentration in another. What they could aim at was to use the maximum concentration tolerated by the eye and hope that that was effective.

Professor Riddell had taken him up on the question of sulphonamide in local infections. He was criticizing the figure as regards the effect of penicillin in ophthalmia neonatorum, particularly the virus infections. The following were the actual figures: 15 virus cases successfully treated with 2,500 units; these were cases which cleared up within from half an hour to ten hours without any relapses; 4 cases relapsed after an initial success; no case was a total failure. In a total of 98 cases of ophthalmia neonatorum due to various causal organisms, the relapses amounted to about 13%, very similar to the percentage obtained in about 700 cases treated with the sulphonamides.

Mr. Greeves had raised an important theoretical point. Professor Sorsby agreed that even if penicillin did not penetrate into the interior of the eye, it might still be of value. It was the ciliary body which held back penicillin from reaching the interior of the eye. He had no definite knowledge of the concentration of penicillin in the ciliary body, but by analogy with the choroidal plexus he thought it might be extremely high, and it was likely that a good deal of this diffused back into the choroid; it was thus possible that choroidal infection would be influenced. The experience of other observers, however, was on record, and most of them had failed to obtain any improvement in choroiditis. The question arose at what stage the choroiditis was treated and the character of the organism. More experience was wanted.

He had been interested to hear Mr. Purvis's account of failure with drops in blepharitis. He himself did not use drops, but painted a solution of penicillin on the lid margins.

In the whole of his experience, which must have embraced considerably more than 500 cases, he had seen allergic response only once. He agreed with Mr. Savin in his criticism. He was not saying that penicillin cured trachoma, but he was reporting it as a possibility to be explored. Treatment in that particular case was exclusively with penicillin, apart from the expression.

[November 9, 1945]

Neuro-retinitis of Unknown Origin.—NIGEL CRIDLAND, D.M.

Mr. Cridland said that he had seen the patient who was 24 years old in Colombo three years ago and had been hoping to obtain an opinion on it ever since. The original complaint was a diminution of the field of vision. There was no clue to the cause and the fundus was normal when first examined. At that time, six months after the onset of symptoms, the field to 5/320 white was reduced to 5° from the fixation point. Visual acuity was 6/5.

Three months later, as no cause had been found, he trephined the right eye in the hope of increasing the retinal circulation and so of arresting, or at any rate, delaying the field loss (which had reached the figure of 3° from the fixation point at the time of operation).

After recovery from operation the field was 23½°, central vision was 6/5 corrected and the field had remained unchanged from that time until now. Central vision was also unaltered after operation. The only fundus abnormalities were a few fine flecks of pigment along the inferior nasal vein and a suggestion of a very mild diffuse retinal oedema.

To-day the fundus appearances were those of a fine diffuse chorio-retinitis.

Mr. Cridland said that the only possible cause which had appeared in the history was two courses of sulphapyridine given for gonorrhœa but he was very doubtful of the significance of this and he invited comment or suggestions as to ætiology. It was, however,

(2) *Penicillin in Experimental Infections*

(1) *Corneal infections*.—There is no adequate experimental lesion of the cornea for testing the value of penicillin in its various modes of application.

(2) *Inoculation into the anterior chamber*.—The use of corneal baths and ionization after infecting the anterior chamber with pneumococcus and *Staphylococcus aureus* gave mostly satisfactory results.

(3) *Inoculation of Staphylococcus aureus into the vitreous*.—Systemic administration of penicillin gave no results. Injection of penicillin into the anterior chamber and subconjunctivally produced some control. Injection into the vitreous gave good results, the best being when quantities of more than 1,000 units were used.

(3) *Clinical Findings*

(1) *Systemic administration*.—Reports are conflicting. Cures in reported cases have largely been in external infections (ophthalmia neonatorum, gonococcal conjunctivitis). Intraocular infections have mainly not responded.

(2) *Local applications*.—A large number of reports give satisfactory results with solutions and ointments in blepharitis, acute conjunctivitis and superficial corneal ulcers. Good results have also been obtained in hypopyon ulcer. Reports on treatment of infected socket are conflicting.

(3) Irrigation of an infected anterior chamber and the injection of penicillin in such lesions have given good results.

(4) *Subconjunctival and intravitreal injections*.—No adequate data are as yet available.

(5) Penicillin in the form of drops has been used for a series of 123 cases of ophthalmia neonatorum. The best results are obtained with a concentration of 2,500 units per c.c., the drops being given at frequent intervals. When instilled at one-minute intervals purulent discharge is controlled within half an hour.

(6) The possible use of penicillin in trachoma and interstitial keratitis is indicated on the basis of a small series.

For full References see SORSBY, A. (1945) *Brit. J. Ophthalm.*, 29, 511.

Mr. D. V. Giri asked whether ionization of penicillin had been tried in septic inflammation of the interior of the eye or in septic inflammation arising after operations for cataract. What was the effective concentration of penicillin which should be used?

Prof. W. J. B. Riddell asked why parenteral administration should not be given at a high level to ensure that penicillin did penetrate the eye. Was it still a question of supply or was there any technical reason against it?

He considered that there was a potential danger in ointment bases being used for lowering surface tension or lowering interface tension. These detergent mixtures might well cause damage to the eye, and care must be taken in dealing with such substances.

He did not consider that full justice was given to the work of Robson and Scott. The lesion they produced was a reasonably standard one. Granting that it did not lead to the destruction of the eye, it was still of great importance in research into eye conditions if the time of healing could be accelerated. It was very advantageous if this could be achieved by the use of penicillin.

Mr. R. Affleck Greeves said that the fact that penicillin administered systemically did not appear in the aqueous did not necessarily mean that it did not penetrate the tissues of the uveal tract and retina. He quoted 2 cases in point, in which syphilitic uveitis and retinitis respectively had quietened down after the systemic use of penicillin. He knew, of course, that many intra-ocular inflammations were probably allergic rather than bacterial, but even so blood-borne penicillin might conceivably operate by attacking a distant septic focus of infection. He also desired to ask whether there was any evidence that penicillin given systemically could penetrate the cornea. He had had one case of hypopyon ulcer which he treated with penicillin in that way and which did extremely well.

Mr. V. B. Purvis said that they all hoped that penicillin would help in cases of intra-ocular infection, although, as Professor Sorsby had pointed out, penicillin did not enter the interior of the eye. Might there not be some indirect effect? Had not the time come when they might be recommended to use penicillin before an eye operation? He had not been successful with drops in the treatment of blepharitis. A technical point was that the ointment base with which they were often supplied went hard and to that extent was unusable. In general the effect of penicillin was remarkable. While it might have no direct effect, he had found it most helpful in intra-ocular infections.

vitamin B tablets which were issued by the Japanese and he also managed to buy some ten eggs monthly.

His vision failed quite quickly—over a period of two days—in December 1942, and then recovered slowly during the following year after which he was of the opinion that it had remained stationary.

When seen on June 6 last he had temporal pallor of both discs and central vision was reduced to 3/60 in the right and 6/36 in the left eye—both not improved, but peripheral fields were full to a 2/330 white target. I referred him to Lieut.-Colonel Hargreaves i/c Medical Division at Millbank as a case of nutritional retrobulbar neuritis and he agreed with me that the optic atrophy was the result of malnutrition. No other physical signs of disease were found in this patient apart from the pallor of the discs and some dental caries and as he was eager to return to his home in Canada for domestic reasons he was allowed to proceed without further delay.

CASE II.—Sgt. D. G., aged 29, who was admitted to Shenley Military Hospital on July 18, 1945. He had been taken prisoner at Mulmein, Southern Burma, on May 19, 1942, was kept there for a month and then moved to Rangoon where he remained until he managed to escape a few days before the 14th Army reoccupied that city, reaching the British lines on May 12, 1945.

At Mulmein his diet consisted almost wholly of polished rice with a little bean soup. At Rangoon the diet was more plentiful but for the first twelve months consisted largely of rice with a small amount of vegetables (potatoes, marrow, cucumber, pumpkin), and lesser quantities of meat and sugar. Thereafter the prisoners' rations were increased somewhat, they received more meat, and rice sweepings were added to the diet.

Sgt. D. G. (November 1, 1945). Showing peripheral fields to a 1° white object, paracentral scotomata and blind spots to a 2/1000 white target and pallor, mainly temporal, of the optic discs.

On July 14, 1943 (his birthday!) whilst reading a book his vision suddenly failed and he was unable to finish the novel. For three months prior to this he had been suffering from pain and numbness in his legs and had experienced some difficulty in balancing himself; there was no swelling of his ankles. He was in a hospital (of sorts!) at the time of his visual loss receiving treatment for dysentery. The pain and numbness in his legs improved slightly with the addition of rice sweepings to his diet, but he did not notice any change in his vision. He had been wearing glasses for the correction of a small degree of myopia prior to his capture but these were taken from him by the Japanese.

He was in hospital in India in June, and the first half of July 1945, and was then evacuated to the U.K. by air. I first saw him on July 19, 1945, the visual acuity of the

right eye was then $< 6/60 \text{ e} - 3.25 \text{ sph.} = 6/60$, that of the left $< 6/60 \text{ e} - 0.50 \text{ sph.} = 6/60$, — peripheral fields full, scotometry was unreliable as the patient could not fixate and the fundi showed fairly generalized pallor of the discs. He was put on a full diet with three multivite tablets three times a day to date and in addition received injections of Benerva—25 mg.—daily for seven days in July and a further course of Benerva injections for a fortnight in October 1945.

Sgt. D. G. is of the opinion that his vision has improved since his return to this country and on November 1, 1945, his corrected vision was R. 6/36 and L. 6/24, peripheral fields were full, scotometry showed paracentral defects and the discs no appreciable change.

remarkable that the field had remained unchanged for three years after operation despite the enormous early loss.

Mr. E. F. King thought this was a case of widespread superficial choroiditis. The changes in the retina were secondary.

Ocular Myiasis.—R. J. V. PULVERTAFT, M.B.

Myiasis affecting the eye is stated to be not uncommon in the natives of Upper Egypt. Three cases were noted in British troops in the Tel-el-Kebir area, in a period of nine months.

The first two cases were very similar, the patient complaining that he had had a "fly in the eye" and could not get it out. On examination minute larvæ were found in the conjunctival sac. [A photomicrograph of one of these was shown.]

The third case was a patient suffering from a blind, painful eye resulting from a battle injury. After removal the eye reached the laboratory, and when cut open revealed a fully developed larva in the posterior chamber.

The conjunctival larva was provisionally diagnosed by an entomologist as *æstrus* ovis.

It is stated that cases of conjunctival myiasis were also recorded in the Alexandria area.

Mr. A. F. MacCallan said that they were indebted to Dr. Pulvertaft for exhibiting the photomicrograph of a larva from the conjunctival sac and the specimen showing a larva in the posterior chamber. [Not published.] The identification of the conjunctival larva as that of *æstrus* ovis was of interest as it had not previously been reported in the *Bulletin of the Ophthalmological Society of Egypt* as infesting the eye. *Onchocerca volvulus* had been reported by Barrada (1934) at the macula; an illustration of the case was shown in Duke-Elder's Textbook. Extra-ocular infestation by *Filaria bancrofti* had been reported by Sobhy (1922).

Every year a number of patients with ocular myiasis or fly-blown orbit were seen at the Egyptian ophthalmic hospitals. These had all been due to *Wohlfartia magnifica*, an arthropod. This fly was viviparous, settling on the conjunctiva for a fraction of a second it deposited active larvæ which started burrowing in the fornices at once. Children and elderly or infirm persons were usually attacked. The conditions produced were sometimes terrible. A single case of bilharziasis of the conjunctiva had been reported by Sobhy.

BARRADA, M. A. (1934) *Bull. Soc. Ophthal. Égypte*, 27, 63.

SOBHY, M. (1922) *Bull. Soc. Ophthal. Égypte*, 15, 51.

Mr. Frank Juler asked how the fly got inside the eye.

Dr. Pulvertaft replied that the maggot actually ate its way through to the sclera or cornea.

Myotonic Pupils with Unilateral Myosis on Drinking Cold Water.—JAMES CRAN, M.B., Ch.B. (introduced by Mr. EUGENE WOLFF).

Dr. Cran said that this was the case of a woman aged 21, first seen on July 5, 1945. She had contraction of the left pupil on drinking cold water. The patient was seen by Mr. Wolff on the same day who reported that vision was normal, fundi were normal; the pupils were central, circular, equal, did not react to light, but reacted very sluggishly to convergence.

Although the patient might have myotonic pupils knee-jerks could be elicited on reinforcement.

No other abnormality was found on complete physical examination.

The Wassermann reaction was negative.

Mr. Eugene Wolff said that it was extremely difficult to see how the reflex could have any relation to the 3rd nerve.

Dr. Cran, in reply to questions, said that he understood the same reflex was not forthcoming to warm water. Moreover, it was elicited only when the water was actually swallowed, not when it was held in the mouth.

Nutritional Retrobulbar Neuritis

By LIEUT.-COLONEL C. DEE SHAPLAND, R.A.M.C.

A NUMBER of our prisoners of war now returning from Japanese prison camps show signs of a past retrobulbar neuritis, almost certainly nutritional in origin, and as this condition does not appear to have been widely recognized in this country the demonstration and description of a few cases may be of interest.

CASE I.—Was seen at Millbank on June 6, 1945.

Major N. I. M., aged 38, of the I.M.S., had been captured by the Japanese in February 1942, and set free when the 14th Army entered Rangoon. His diet from February 1942 to May 1945 consisted mainly of polished rice with very occasional vegetables, dried fish and pork. During the last two years of his captivity he was able to get yeast and

vitamin B tablets which were issued by the Japanese and he also managed to buy some ten eggs monthly.

His vision failed quite quickly—over a period of two days—in December 1942, and then recovered slowly during the following year after which he was of the opinion that it had remained stationary.

When seen on June 6 last he had temporal pallor of both discs and central vision was reduced to 3/60 in the right and 6/36 in the left eye—both not improved, but peripheral fields were full to a 2/330 white target. I referred him to Liéut.-Colonel Hargreaves i/c Medical Division at Millbank as a case of nutritional retrobulbar neuritis and he agreed with me that the optic atrophy was the result of malnutrition. No other physical signs of disease were found in this patient apart from the pallor of the discs and some dental caries and as he was eager to return to his home in Canada for domestic reasons he was allowed to proceed without further delay.

CASE II.—Sgt. D. G., aged 29, who was admitted to Shenley Military Hospital on July 18, 1945. He had been taken prisoner at Mulmein, Southern Burma, on May 19, 1942, was kept there for a month and then moved to Rangoon where he remained until he managed to escape a few days before the 14th Army reoccupied that city, reaching the British lines on May 12, 1945.

At Mulmein his diet consisted almost wholly of polished rice with a little bean soup. At Rangoon the diet was more plentiful but for the first twelve months consisted largely of rice with a small amount of vegetables (potatoes, marrow, cucumber, pumpkin), and lesser quantities of meat and sugar. Thereafter the prisoners' rations were increased somewhat, they received more meat, and rice sweepings were added to the diet.

Sgt. D. G. (November 1, 1945). Showing peripheral fields to a $\frac{1}{2}^\circ$ white object, paracentral scotomata and blind spots to a 2/1000 white target and pallor, mainly temporal, of the optic discs.

On July 14, 1943 (his birthday!) whilst reading a book his vision suddenly failed and he was unable to finish the novel. For three months prior to this he had been suffering from pain and numbness in his legs and had experienced some difficulty in balancing himself; there was no swelling of his ankles. He was in a hospital (of sorts!) at the time of his visual loss receiving treatment for dysentery. The pain and numbness in his legs improved slightly with the addition of rice sweepings to his diet, but he did not notice any change in his vision. He had been wearing glasses for the correction of a small degree of myopia prior to his capture but these were taken from him by the Japanese. He was in hospital in India in June, and the first half of July 1945, and was then evacuated to the U.K. by air. I first saw him on July 19, 1945, the visual acuity of the right eye was then $< 6/60 \text{ } \varepsilon - 3.25 \text{ sph.} = 6/60$, that of the left $< 6/60 \text{ } \varepsilon \xrightarrow{-3.50} \xrightarrow{-0.50} = 6/60$, — peripheral fields full, scotometry was unreliable as the patient could not fixate and the fundi showed fairly generalized pallor of the discs. He was put on a full diet with three multivite tablets three times a day to date and in addition received injections of Benerva—25 mg.—daily for seven days in July and a further course of Benerva injections for a fortnight in October 1945.

Sgt. D. G. is of the opinion that his vision has improved since his return to this country and on November 1, 1945, his corrected vision was R. 6/36 and L. 6/24, peripheral fields were full, scotometry showed paracentral defects and the discs no appreciable change.

CASE III.—Pte. L. Frank, aged 25, was referred to me by Major Mrs. Stewart from the Royal Herbert Hospital, Woolwich, on September 9 of this year. He had been taken prisoner by the Japanese in April 1943, and was in Rangoon for just two years before being set free on April 30, 1945.

His vision failed in both eyes in December 1943, since when there had not been much recovery. During the middle twelve months or so of his captivity he had experienced difficulty in walking and much pain in his toes.

He showed temporal pallor of both discs with vision reduced to 6/36 in the right and 1/60 in the left eye, both not improved. Peripheral fields were full but the right showed a pericentral and the left a central scotoma—absolute—to a 1/330 white object. Blood Wassermann and Kahn were negative. X-ray of the skull showed the sella turcica and the remainder of the skull to be within normal limits and there was no evidence of raised intracranial pressure. There was no confirmatory evidence of disseminated sclerosis.

His diet as a P.O.W. was largely polished rice and there seems no doubt that he had suffered from "dry" beri-beri complicated by a nutritional retrobulbar neuritis.

Since the arrival in this country in the last two weeks of October 1945 of a number of transports bringing repatriated prisoners mainly from Singapore several further examples of this condition have been seen at Millbank amongst whom was Captain E. D. H. Williams, aged 33, of the R.A.M.C. He was taken prisoner at Singapore on February 15, 1942, and was in the prison camp at Changi on Singapore Island during the whole of his captivity. His staple diet was polished rice but with additions. His vision began to deteriorate early in May 1943, and at the end of the month the acuity was about 6/9 R. and L. but with small pericentral scotomata. He was put on 4 oz. of rice polishings a day but this gave him severe diarrhoea and a fortnight later his central vision had gone down to 6/60 in each eye. An ounce of marmite a day was then substituted for the rice polishings with considerable improvement to his visual acuity which in about a month had risen to 6/18 R. and L. From June to September 1945 Captain Williams suffered from angular stomatitis and had some transient oedema of the ankles.

When seen at Millbank on October 29 last his central vision was 6/18 pt. R. and L. not improved, the media of both eyes were clear and the fundi normal except for slight temporal pallor of the discs; peripheral fields were full and there were small pericentral scotomata.

The association of a retrobulbar neuritis with beri-beri is by no means new although I could find no reference to it in the Official History of the War (1914-18). In 1895, Kono published 6 cases of beri-beri associated with amblyopia, central scotoma and contraction of the visual field, but presenting no fundus changes. Three years later, Komoto discovered that the cause of the amblyopia and of the central scotoma was to be sought in a retrobulbar neuritis and added that the scotoma began centrally and spread centrifugally. Yamamoto seems to have been the first (1903) to draw attention to an atrophic condition of the temporal side of the disc in these cases, whilst Kagoshima in 1918 made an anatomical examination of five cases in which kakke-scotoma was present and found in all of them a distinct and limited atrophy of the fibres in the outer section of the optic nerve.

Elliot in his Tropical Ophthalmology (1920) from which source the above Japanese references were obtained states the signs of retrobulbar neuritis fall under three headings: (1) central scotoma, (2) diminution of the central visual acuity, and (3) changes in the visual field. In the earlier stages, the scotoma is of small size, and according to Miyashita it is connected with the blind spot by a narrow bridge, thus giving it what he speaks of as "its most characteristic pestle-shaped form". Ishihara described the defect as having an irregular, elongated oval form in one case and as being half-moon-shaped in another, whilst Aoki described the white and colour scotomata as nearly always obliquely oval and added that the size of the latter diminished in the order, green, red and blue.

According to Miyashita whilst the scotoma enlarges, the central vision gradually falls till it reaches the low limit of 6/60; he adds that it seldom goes lower than this. It is this interference with vision which leads the patient to seek medical relief, and thus results in the recognition of the diagnostic sign of central scotoma.

With regard to changes in the visual field Elliot states that these would appear to vary very greatly in different cases. Many writers make no reference to any constriction of the peripheral fields either for white or for colours, indeed Coppez went out of his way to record that peripheral vision was undamaged in his case. Ishihara stated that contractions of the visual field occur, but were transitory in nature, whilst Yamaguchi found no marked contraction of the white field, but that those for red and green were shrunken. It is of interest in this connexion to note that though atrophy of the papillo-macular bundle is of not infrequent occurrence in these cases, a general optic atrophy is apparently quite rare.

Later work and observations, more especially by Fitzgerald Moore (1945) in West Africa and by H. S. Stannus (1944) in this country, have led to the view that the type of retrobulbar neuritis here described is part of a syndrome characterized by sore tongue with cracked lips, dry furfuraceous skin, dry scaly scrotum and by various nervous manifestations, which, apart from loss of visual and auditory acuity, consist of mental dullness, a sense of muscular weakness, ataxia and paræsthesiæ, the whole syndrome

being ascribed largely to riboflavin deficiency, though probably other factors of the B complex are involved.

As regards treatment Fitzgerald Moore found it worth while to treat all cases having a history up to twelve months. Over that period improvement was problematical unless the patient was still suffering from subacute effects of his malnutrition. Cases in which a diminution of vision had become manifest in less than a year generally showed a good prognosis and those with a history of six months or less an excellent one. He gave 1 oz. of marmite a day and continued this high dosage over a period of at least six months. In favourable cases visual response commenced within three to six weeks, usually about "One Snellen line a fortnight", others were much slower while a considerable number had reached an irreversible stage and did not improve. Occasionally, however, unexpected and un hoped-for results were obtained in cases where all the signs suggestive of irreversible changes had intervened and for that reason alone he was of the opinion that persistence in treatment was always justified.

Fitzgerald Moore also points out the importance in these cases of better class and more varied carbohydrates and stresses the danger of certain staple carbohydrate foodstuffs such as rice, manioc, sago and sugar-cane when eaten to excess where the general dietary itself is poorly balanced.

Many of the patients I have seen found that their symptoms, including loss of visual and auditory acuity, were temporarily exacerbated following their liberation and the subsequent institution of a full diet. This, with further observations, was noted by Captain E. D. H. Williams who was a prisoner himself at Changi for three and a half years.

 STANNUS, H. S. (1944) *Brit. med. J.* (ii), 103 and 140.

Captain E. D. H. Williams, who had been for three and a half years a prisoner at Changi, said that possibly the circumstances of the captivity itself accounted for a rather defective memory.

The main carbohydrate diet the whole time was rice. During the first year they had up to 20 oz. a day, but later it was cut down to 14 oz., and that went on for a further six months until 1944 (June). During the next six months there was a slight improvement, but by Christmas 1944 they were very short of rice. Substitutions for this diet were meat, and there was a good deal of mutton and beef available for the first nine months, and they had a fair proportion of that meat. Afterwards fish was almost the only protein available, including something called whitebait (which, however, did not taste like it), and of this they had about 1 oz. a day, usually rather less. After the first six months they got some Red Cross goods—bully beef and milk—and again a year later, and again in June 1945 a more varied quantity, with a certain amount of fish, cheese, butter—and rice! At one period a certain number of sardines became available, and these seemed to have a good effect on the people generally. The black period was after Christmas 1942. Green vegetables grown by the captives were sometimes available, but the supply of these depended upon whether the camp was moved or not. At the beginning of 1944, under the influence of the Americans, maize was cooked in wood ash, and, whether as a consequence of this or not, a large number of people developed what they thought to be pellagra. Neuritic beri-beri started early and was seen particularly in people who had taken a large quantity of alcohol. Later on it appeared to be connected with people who got dysentery, and later still it became so complicated that nobody knew what its cause was. The oedematous form of beri-beri started rather later, and seemed to be connected in certain cases with achlorhydria. Some dozen cases of spastic paraplegia he saw seemed to be permanent with one marked exception. One post-mortem showed the white matter of spinal cord studded with necrotic areas the size of millet seeds. These deficiencies did not seem to be connected with retrobulbar neuritis, but this was apparent in a second group of cases in which there was what was considered to be riboflavin deficiency. Scrotal dermatitis was seen very frequently. The severe conditions were seen starting again about February of this year and reaching their height in August and September, when people were found dying suddenly. With the return to normal food the eye conditions did not worsen as did oedematous and cardiac forms of avitaminosis.

Mr. M. L. Hine said that only the previous week he had seen a civilian who had returned from Hong Kong, and who told him that a few months after being in the camp he had central blindness and could not read at all for some months. The Japanese gave him some vitamin tablets. When he mentioned to him the name "nicotinic acid", he recalled that they gave him some of that too. He recovered, and, when he was seen, his fundus was normal and vision 6/5 with no scotoma. This confirmed what Colonel Shapland had said about the good outlook if treatment were early enough.

Dr. R. J. V. Pulvertaft said that there was an epidemic of this sort in the British war camp at Suez. An attack of pellagra in Libyan and German prisoners was attributed to illicit stills which were thought to be making methyl alcohol. The case was investigated, but it seemed from the evidence to have been a true dietetic deficiency. In May

CASE III.—Pte. L. Frank, aged 25, was referred to me by Major Mrs. Stewart from the Royal Herbert Hospital, Woolwich, on September 9 of this year. He had been taken prisoner by the Japanese in April 1943, and was in Rangoon for just two years before being set free on April 30, 1945.

His vision failed in both eyes in December 1943, since when there had not been much recovery. During the middle twelve months or so of his captivity he had experienced difficulty in walking and much pain in his toes.

He showed temporal pallor of both discs with vision reduced to 6/36 in the right and 1/60 in the left eye, both not improved. Peripheral fields were full but the right showed a pericentral and the left a central scotoma—absolute—to a 1/330 white object. Blood Wassermann and Kahn were negative, X-ray of the skull showed the sella turcica and the remainder of the skull to be within normal limits and there was no evidence of raised intracranial pressure. There was no confirmatory evidence of disseminated sclerosis.

His diet as a P.O.W. was largely polished rice and there seems no doubt that he had suffered from "dry" beri-beri complicated by a nutritional retrobulbar neuritis.

From June to September 1945 Captain Williams suffered from angular stomatitis and had some transient oedema of the ankles.

When seen at Millbank on October 29 last his central vision was 6/18 pt. R. and L. not improved, the media of both eyes were clear and the fundi normal except for slight temporal pallor of the discs; peripheral fields were full and there were small pericentral scotomata.

The association of a retrobulbar neuritis with beri-beri is by no means new although I could find no reference to it in the Official History of the War (1914-18). In 1895, Kono published 6 cases of beri-beri associated with amblyopia, central scotoma and contraction of the visual field, but presenting no fundus changes. Three years later, Komoto discovered that the cause of the amblyopia and of the central scotoma was to be sought in a retrobulbar neuritis and added that the scotoma began centrally and spread centrifugally. Yamamoto seems to have been the first (1903) to draw attention to an atrophic condition of the temporal side of the disc in these cases, whilst Kagoshima in 1918 made an anatomical examination of five cases in which kakke-scotoma was present and found in all of them a distinct and limited atrophy of the fibres in the outer section of the optic nerve.

Elliot in his *Tropical Ophthalmology* (1920) from which source the above Japanese references were obtained states the signs of retrobulbar neuritis fall under three headings: (1) central scotoma, (2) diminution of the central visual acuity, and (3) changes in the visual field. In the earlier stages, the scotoma is of small size, and according to Miyashita it is connected with the blind spot by a narrow bridge, thus giving it what he speaks of as "its most characteristic pestle-shaped form". Ishihara described the defect as having an irregular, elongated oval form in one case and as being half-moon-shaped in another, whilst Aoki described the white and colour scotomata as nearly always obliquely oval and added that the size of the latter diminished in the order, green, red and blue.

According to Miyashita whilst the scotoma enlarges, the central vision gradually falls till it reaches the low limit of 6/60; he adds that it seldom goes lower than this. It is this interference with vision which leads the patient to seek medical relief, and thus results in the recognition of the diagnostic sign of central scotoma.

With regard to changes in the visual field Elliot states that these would appear to vary very greatly in different cases. Many writers make no reference to any constriction of the peripheral fields either for white or for colours, indeed Coppez went out of his way to record that peripheral vision was undamaged in his case. Ishihara stated that contractions of the visual field occur, but were transitory in nature, whilst Yamaguchi found no marked contraction of the white field, but that those for red and green were shrunken. It is of interest in this connexion to note that though atrophy of the papillo-macular bundle is of not infrequent occurrence in these cases, a general optic atrophy is apparently quite rare.

Later work and observations, more especially by Fitzgerald Moore (1945) in West Africa and by H. S. Stannus (1944) in this country, have led to the view that the type of retrobulbar neuritis here described is part of a syndrome characterized by sore tongue with cracked lips, dry furfuraceous skin, dry scaly scrotum and by various nervous manifestations, which, apart from loss of visual and auditory acuity, consist of mental dullness, a sense of muscular weakness, ataxia and paresthesiæ, the whole syndrome

Fig. 2 shows a zonular fibre becoming continuous with the zonular fibre of the anterior capsule.

This fibre is one of the orbiculo-anterior capsular fibres, the longest and strongest fibres of the zonule. They arise from the pars plana and receive auxiliary fibres along their whole course. They lie in the valleys between the taller ciliary processes, where they form well-marked bundles.

Most of the auxiliary fibres run from behind forwards and inwards, but just behind the posterior ciliary processes they also run from in front backwards and inwards. The zonular fibres here, therefore, have a double attachment which makes for strength and so it is usually just beyond this point that the fibres break.

Are there any equatorial fibres? The answer lies in the development and natural history of the zonule.

FIG. 2.—Zonular fibre becoming continuous with the zonular fibre of the anterior capsule. $\times 250$. Ant. post. section.

In the embryo and at birth there are a great many more fibres than in the adult. These arise not only from the inner aspect of the ciliary body but from the back of the iris, the angle of the posterior chamber and from the most anterior ciliary process which in the adult lies free from zonular fibres. Also on the lens capsule the space between the anterior and posterior groups of fibres is entirely filled in by equatorial fibres. With age, many of these equatorial fibres disappear and only a few sparse ones or none at all may

CASE III.—Pte. L. Frank, aged 25, was referred to me by Major Mrs. Stewart from the Royal Herbert Hospital, Woolwich, on September 9 of this year. He had been taken prisoner by the Japanese in April 1943, and was in Rangoon for just two years before being set free on April 30, 1945.

His vision failed in both eyes in December 1943, since when there had not been much recovery. During the middle twelve months or so of his captivity he had experienced difficulty in walking and much pain in his toes.

He showed temporal pallor of both discs with vision reduced to 6/36 in the right and 1/60 in the left eye, both not improved. Peripheral fields were full but the right showed a pericentral and the left a central scotoma—absolute—to a 1/330 white object. Blood Wassermann and Kahn were negative, X-ray of the skull showed the sella turcica and the remainder of the skull to be within normal limits and there was no evidence of raised intracranial pressure. There was no confirmatory evidence of disseminated sclerosis.

His diet as a P.O.W. was largely polished rice and there seems no doubt that he had suffered from "dry" beri-beri complicated by a nutritional retrobulbar neuritis.

Since the arrival in this country in the last two weeks of October 1945 of a number of transports bringing repatriated prisoners mainly from Singapore several further examples of this condition have been seen at Millbank amongst whom was Captain E. D. H. Williams, aged 33, of the R.A.M.C. He was taken prisoner at Singapore on February 15, 1942, and was in the prison camp at Changi on Singapore Island during the whole of his captivity. His staple diet was polished rice but with additions. His vision began to deteriorate early in May 1943, and at the end of the month the acuity was about 6/9 R. and L. but with small pericentral scotomata. He was put on 4 oz. of rice polishings a day but this gave him severe diarrhoea and a fortnight later his central vision had gone down to 6/60 in each eye. An ounce of marmite a day was then substituted for the rice polishings with considerable improvement to his visual acuity which in about a month had risen to 6/18 R. and L. From June to September 1945 Captain Williams suffered from angular stomatitis and had some transient oedema of the ankles.

When seen at Millbank on October 29 last his central vision was 6/18 pt. R. and L. not improved, the media of both eyes were clear and the fundi normal except for slight temporal pallor of the discs; peripheral fields were full and there were small pericentral scotomata.

The association of a retrobulbar neuritis with beri-beri is by no means new although I could find no reference to it in the Official History of the War (1914-18). In 1895, Kono published 6 cases of beri-beri associated with amblyopia, central scotoma and contraction of the visual field, but presenting no fundus changes. Plastic Artificial Eyes

By Squadron Leader F. J. STEWART, R.A.F.

SQUADRON LEADER STEWART spoke briefly on the subject of plastic eyes. His experience in plastics up to four or five years ago had been confined to plastic dentures and plastic teeth, but his observations from R.A.F. patients with glass eyes suggested that plastics might be used in these cases with considerable advantage.

He briefly enumerated some ten defects of the glass eye, such as fragility, surface erosion, imperfect fit, light reflection, weight, &c. Plastics on the other hand, he claimed, overcame these difficulties, and two or three years' tests in patients' sockets confirmed this. Against plastic eyes there was always the possibility of a person having an idiosyncrasy to the material (methyl methacrylate) though no case had occurred in some two or three hundred cases that he had studied; in American literature it was stated that it existed in one in ten thousand.

With present technique the cost of acrylic eyes was considerably more than glass as it involved the taking of impression and building up each eye individually. Plastic eyes were being mass produced very cheaply, though by this means many of the advantages of plastic were lost, but on the grounds of permanence and lightness plastic still had advantages over its glass counterpart.

Specimen cases of glass eyes and their defects and plastic eyes in the various stages of construction to the finished article were on display.

Mr. D. V. Giri asked what it would cost a patient to have a plastic eye made for him. At the Southern Ophthalmological Society two weeks previously a patient was demonstrated who had been fitted with a plastic eye which was a marvellous match, so that it seemed there were people already making plastic eyes. With regard to the time for which glass eyes lasted, not very long ago he had come across a patient who had kept the same eye for eight years, and it was a wonderful match.

A Visitor asked who it was proposed should make these plastic artificial eyes in the future. The author had said that the eye might be taken out and washed. It had fallen to his lot to provide skin linings for sockets, and he had always been troubled by the amount of discharge. The discharge seemed to increase when the artificial eye was inserted. This discharge might last a long time, and it was one of their great difficulties to stop it. Was any experience available concerning the supply of eyes to skin-lined sockets? Had such skin linings any disadvantage?

Dr. Margaret Dobson asked whether the material used for plastic artificial eyes was the same as for plastic lenses. She knew little about plastic artificial eyes but a good deal about plastic lenses. She had ordered quite a number of them and wore plastic spectacles herself. The trouble was that they scratched so very easily. She recalled that one of her duties in the first European war was to do a good deal of fitting for glass eyes, and that and subsequent experience made her stand up for the glass eye, which might be beautifully made and most comfortably fitted, if made for each individual case by an expert. Mass-produced eyes were often found to fit badly.

Mr. Victor Purvis said that he was reminded of a case he saw last year, that of an old agricultural labourer who had worn an artificial eye continuously in the same socket day and night and had never taken it out for fifteen years. He had now broken the eye and wanted to know what he should do with the remnants in the socket.

Mr. Frederick Ridley said that he had had experience in the Facio-maxillary Unit at East Grinstead during the war in connexion with the reconstruction of sockets in order to carry a prosthesis. It was found that it was first necessary to distend the socket and to keep it distended. Too little attention was often paid to the preparation of the socket for the eye. Unless the patient had been wearing an adequate glass shell or some form of prosthesis one's first duty was to distend the socket if a good cosmetic result was to be obtained, otherwise the eye would appear unnecessarily small. The author had raised the question of motility. At East Grinstead they found that the best thing to do was to use a prosthesis as a temporary filling which had a conical hollow at the back, rather like the shell eye with which they were familiar. If there was a hollow in the back of the prosthesis, the soft tissues were easily moulded so that a mobile stump or cone, as it was called, was very quickly formed; this cone contains the ends of the muscles. Over this stump the eye could be built up and good movement obtained. It had been asked what was the effect of the acrylic prosthesis on the discharging skin-lined sockets. It was inert. In his experience the discharge was unavoidable, whatever sort of prosthesis was worn.

or June of last year he saw a number of persons in this condition among prisoners back from the Philippines. They had a certain amount of blindness and were mentally very dull. Speaking the previous week to the O.C. of the Medical Division, he said that he was not satisfied that anything but the retrobulbar neuritis was an entity; the other things might be hysterical. A medical officer who had been a prisoner of war for three years was of opinion that the whole thing was due to methyl alcohol, which was obtainable in all the prisoner of war camps, and would not have it that these cases were vitamin deficiency at all.

Major A. J. Cameron said that similar cases from the Far East which he had seen seemed to fall into definite groups. The first and smallest was a group in which the pathological findings at the disc were very obvious, visual depression very marked, and an estimation of the visual field only possible by gross confrontation. In the second and by far the largest group there was very little to be seen at the disc and in many cases certainly not more temporal pallor than was frequently found in normal eyes. The visual acuity was not greatly depressed, often being as good as 6/12 or 6/9, but the patient complained of what could be described as "central symptoms". Examination of the field of vision on the perimeter and on the Bjerrum screen showed small scotomata in the paracentral area. In many such cases the scotomata were larger and centro-caecal in type and so much resembled the form of scotoma obtained in that form of chronic retrobulbar neuritis known as tobacco amblyopia that it prompted an inquiry along those lines. He was able to find out that smoking was very prevalent. No tobacco was available from home, and the men smoked what was described as a native leaf. This they all said was stronger than anyone ever smoked in this country. Perhaps that was a factor which should be borne in mind.

The third group was composed of those who exhibited no objective symptoms. The vision was good and their fields were full. It was difficult to decide whether they were functional or were remembering a previous train of symptoms. All these soldiers were well aware of what was meant by vitamin deficiency and they all endeavoured to get their share of rice polishings, red palm oil, grass extract, &c. Notes on production of vitamin preparations in the camp by the prisoners themselves had been furnished to him by Major Burgess, R.A.M.C., formerly of the Malayan Government Medical Service, and Mr. J. H. Piddleston, M.Sc., chemical engineer. These notes were very interesting, but too long to read to the Section. He was indebted to the gentlemen named for the care they had taken in preparing the notes. It was of interest to note that the average duration of "ocular symptoms" was from eight to twelve months, and that many patients found that a return to normal diet and vitamin adjuvants seemed for the time being to exacerbate the visual symptoms. A very frequent symptom was weakness of accommodation.

Mr. F. E. Preston said he had seen a patient who had recently returned to this country. Before the war he had 6/6 vision, and when he saw him his vision was 6/24 in each eye. He diagnosed him as suffering from deficiency disease, but the patient had not complained much about other troubles, he had put down his condition to pure hunger and want of food—he had been fed on rice. The most marked abnormality which he found was his loss of colour sense. He could not do a single one of Ishihara's colour plate tests. He had smoked quite a lot of cigarettes in his hunger—more than he should have done.

Mr. Lindsay Rea said that he could confirm what had been said from the experience of his brother-in-law who had just returned after three and a half years in Japanese hands in Hong Kong. Owing to malnutrition he had suffered from hallucinations of sight such as found in pellagra. A man walking towards him would suddenly appear to throw out his leg sideways like a toy being pulled by a string. This was cured by injections of the vitamin B complex. He was a heavy smoker and got tobacco from the Japanese made from some unknown stuff.

Mr. Lindsay Rea had seen a prisoner-of-war who had been in Germany during the whole of the war. This man, who was in his thirties, had come back with well-marked cataract in each eye of the senile variety; this was progressive. In another man from Sumatra the accommodation had largely failed; his visual acuity was normal. In the cases of non-smokers the retrobulbar neuritis might still be there and might be of the pellagra type but it was as well to inquire what they had been smoking before coming to the conclusion that true retrobulbar neuritis had appeared.

Mr. Affeck Greeves thought that some of these cases might represent something of the nature of toxic amblyopia rather than of retrobulbar neuritis. For example, he had recently seen a man from Guernsey who gave a very accurate description of the symptoms of tobacco amblyopia, and he told him that, in the absence of ordinary tobacco, he had smoked various kinds of dried leaves. The patient's sight recovered completely in spite of the fact that he had resumed the smoking of tobacco as soon as that was obtainable. It was also possible, however, that this type of amblyopia might be the result of malnutrition and not of toxic origin.

Captain E. D. H. Williams, in reply to a member who said that all the cases he had seen had been complicated with malaria, and asked whether that condition was prevalent in the prison camp at Singapore, said that he himself had not had malaria at any time, though he would not like to say what other men got. Malaria was certainly very common in the camp about the end of 1942. In reply to a further question he said that about 1% suffered severe symptoms; they were all under more or less the same conditions.

Fig. 2 shows a zonular fibre becoming continuous with the zonular fibre of the anterior capsule.

This fibre is one of the orbiculo-anterior capsular fibres, the longest and strongest fibres of the zonule. They arise from the pars plana and receive auxiliary fibres along their whole course. They lie in the valleys between the taller ciliary processes, where they form well-marked bundles.

Most of the auxiliary fibres run from behind forwards and inwards, but just behind the posterior ciliary processes they also run from in front backwards and inwards. The zonular fibres here, therefore, have a double attachment which makes for strength and so it is usually just beyond this point that the fibres break.

Are there any equatorial fibres? The answer lies in the development and natural history of the zonule.

These arise not only from the inner aspect of the ciliary body but from the back of the iris, the angle of the posterior chamber and from the most anterior ciliary process which in the adult lies free from zonular fibres. Also on the lens capsule the space between the anterior and posterior groups of fibres is entirely filled in by equatorial fibres. With age, many of these equatorial fibres disappear and only a few sparse ones or— all may

On the question of glass eyes versus other forms of prosthesis, his own feeling was that one could not really improve upon the best glass eyes. For sockets which were in any way distorted or contracted, a moulded acrylic prosthesis was the only possible answer to-day. Too much attention, he thought, had been paid to the restriction to a limited number of sizes and shapes, in criticizing mass-produced eyes, whether glass or acrylic. The normal socket was such that a limited number of sizes and shapes did give excellent results. If money was no object one could have an individual eye made by an artist for every patient. Nevertheless, the mass-produced eye would serve ordinary purposes.

Squadron Leader Stewart, in reply, said that he had trained one or two people to carry out work on artificial eyes, but whether mechanics would be allowed to take impressions of the socket he could not say; mechanics were definitely barred from taking impressions of the mouth, but whether the socket was considered to be inside the body or not was another question.

One of the speakers had already answered the question about discharge. They were neither better nor worse off by using acrylic; if the glass eye fitted badly there seemed to be more discharge. He did not think this had anything to do with the material itself. He had seen only one or two cases in which a skin flap had been put in, and so far he had not been thrilled with the result.

One speaker had asked about the cost. This was a difficult subject. It was more difficult to make an eye than it was to make a denture. What was the price of a denture? He would have thought it not possible to do anything in the way of an artificial eye in plastic under fifteen guineas. Considerable time had to be spent in taking the impression; it was a skilled operation. Some part of the work could be delegated, but by no means all of it. The work was much more difficult than in the case of a denture and the patient was much more critical.

The material was the same as was used for plastic lenses, but admittedly it was scratchable. The lens could not be rubbed even with fine silk without scratching it. There was a method whereby a slight deposit of glass might be made on the surface to give the necessary hardness, but that was still in the experimental stage. He did not think this trouble, while it arose with plastic lenses, need arise with a plastic eye—he had never seen one scratched yet.

Concerning the question of keeping the socket the right size, he liked to get on to the job as soon as possible after the operation. He had not yet quite made up his mind on the question of whether a socket got small or not. They had had patients who had had the eye taken out as children, and one case he saw about a month ago had never had an eye in. The sooner the prosthesis could be inserted so as to give the right size the better. If one had a socket which was shrunk it was very hard to expand it again.

Some Aspects of the Normal Histology of the Suspensory Ligament of the Lens

By EUGENE WOLFF, F.R.C.S.

THERE is still a great deal of dispute even about the main facts of this difficult subject, and latterly, Duke-Elder bringing it into line with the gel theory of vitreous, has suggested that the fibres of the suspensory ligament are "mainly histological artefact".

First one would draw special attention to the most posterior and innermost fibres of the zonule. These, the orbiculo-posterior capsular fibres (fig. 1) arise from the ora serrata and are inserted together with the vitreous, i.e. with the ligamentum hyaloideo-capsulare of Wieger, into the posterior lens capsule. They are everywhere in close contact, indeed, adherent to the anterior limiting layer of the vitreous. Thus if we detach the vitreous many zonular fibres come away with it; if, however, we merely allow the vitreous to flow away the anterior limiting layer remains attached to the posterior zonular fibres (Garnier). Also this close relation of the zonule to the anterior limiting layer is one of the reasons why there is still no unanimous answer to the question: Is there a hyaloid membrane to the anterior vitreous?

Now the anterior limiting layer of the vitreous is not a hyaloid membrane for a hyaloid membrane must be transparent and homogeneous, and have sharp contours. It has more the structure of connective tissue and shows a striation due to its constituent fibrillae parallel to the surface. It is the close relation of the hyaline zonular fibres which is at any rate partly responsible for the error of calling the anterior limiting layer a hyaloid membrane (see Garnier).

Fig. 2 shows a zonular fibre becoming continuous with the zonular fibre of the anterior capsule.

This fibre is one of the orbiculo-anterior capsular fibres, the longest and strongest fibres of the zonule. They arise from the pars plana and receive auxiliary fibres along their whole course. They lie in the valleys between the taller ciliary processes, where they form well-marked bundles.

Most of the auxiliary fibres run from behind forwards and inwards, but just behind the posterior ciliary processes they also run from in front backwards and inwards. The zonular fibres here, therefore, have a double attachment which makes for strength and so it is usually just beyond this point that the fibres break.

Are there any equatorial fibres? The answer lies in the development and natural history of the zonule.

FIG. 1.—Orbiculo-anterior capsular fibres (a); also orbiculo-posterior capsular fibre (b) in close relation with anterior limiting layer of vitreous (c). $\times 250$. Ant. post. section. (Zenker, Mallory's triple stain.)

FIG. 2.—Zonular fibre becoming continuous with the zonular fibre of the anterior capsule. $\times 250$. Ant. post. section.

In the embryo and at birth there are a great many more fibres than in the adult. These arise not only from the inner aspect of the ciliary body but from the back of the iris, the angle of the posterior chamber and from the most anterior ciliary process which in the adult lies free from zonular fibres. Also on the lens capsule the space between the anterior and posterior groups of fibres is entirely filled in by equatorial fibres. With age, many of these equatorial fibres disappear and only a few sparse ones or none at all may

remain. The answer then is that equatorial fibres really only exist in youthful eyes (Garnier).

All are agreed that the attachment of the zonular fibres to the ciliary epithelium is very close. Indeed, if they are pulled away some of the epithelium comes away too.

But there is still a great deal of dispute as to the actual method of fixation. Some say that the zonular fibres are processes of the clear cells of the pars ciliaris retinae; others that the fibres can be followed through these cells to the membrane between them and the pigment layer; others again that the attachment is inter-cellular. I would agree with those who hold that the zonular fibres run into the internal limiting membrane of the ciliary body.

I think the colour photomicrograph of a coronal section of the ciliary body stained by Mallory's triple stain shows this quite clearly. (Illustration omitted owing to space shortage.) The blue staining tissue on the inner aspect of the ciliary body is of special interest. Dejean says that this tissue which stains like collagen is already present at the time of the secondary optic vesicle.

If this is true, then the zonule and further back the vitreous cannot be outgrowths from the ciliary epithelium and retina respectively.

As a general rule the various views with regard to the attachment of the zonule reflect the opinions of the authors on its development.

But there is one aspect of the question which has received very little attention. It is quite well known that the normal pigmented epithelium of the ciliary body proliferates, but that the non-pigmented cells can do this is not usually realized. This epithelium may in fact with age form papillary projections which may be placed so close together that the internal limiting membrane between two elevations may appear inter-epithelial. And if a zonular fibre happens to run into the limiting membrane here it would appear as if its origin too were inter-epithelial.

FIG. 3.—Coronal section of ciliary valley. $\times 300$.

Fig. 3 shows some inter-ciliary fibres of which, so far as I am aware, there is no illustration in the literature.

From what has gone before I need hardly say that I believe the fibres of the suspensory ligament of the lens real, very real. Also it is quite clear from fig. 2 that if the zonular fibre be regarded as an artefact then the capsule of the lens must be an artefact too.

The Nervus Nasalis Complex of Charlin

By MAJOR W. O. G. TAYLOR, R.A.M.C.

Ophthalmic Specialist

THE purpose of this paper is to record in British ophthalmic literature a case of the rather uncommon condition known as the syndrome of the nasal nerve (syn. naso-ciliary nerve) or the nervus nasalis complex of Charlin, and alternative method of treatment.

Case history.—An African soldier in his early twenties was admitted to No. 1 (E.A.) General Hospital on June 15, 1944, with a complaint of pain in his right eye of eight days' duration and unknown cause. On examination the only noteworthy features were blepharospasm and limbal injection; a preliminary diagnosis of iritis was made and the following tests performed:

Conjunctival smear: negative. Kahn test: negative. P.U. smear: no gonococci. Culture: no growth. Urine negative.

Blood-count.—White cells: total 9,400 per c.mm. Differential: Neutros. 37%, eosinos. 3%, lymphos. 52%, monos. 8%.

Treatment.—Ungt. atropinæ 1%, hot spooning, mist. "three fifteens"; each 3 times daily. Four days later it was noticed that beads of sweat gathered on the right side of his nose at the tip, but nowhere else. On wiping them away, they returned within a minute,

and were sharply limited to the terminal distribution of the external cutaneous branch of the right naso-ciliary nerve. The patient stated that this had begun at the same time that his eye began to feel sore.

Slit-lamp examination: Many fine keratic precipitates.

22.6.44: X-ray—sinuses normal.

By July 5, the case had improved so that the sweating was no longer visible, although it could be readily induced in the same distribution by momentary exposure of the face to a radiant heat lamp. At this stage the photograph (fig. 1) was taken.

7.7.44: Slit-lamp examination—K.P. now much larger. Ophthalmoscope—fundus oculi still not visible.

On July 18, the eye was quiet but the vision of the right eye less than 6/60 (V.A.L. 6/6), due to haze of the media. On July 22, there was an acute relapse of both the iritis and the sweating. X-ray examination was repeated and reported as follows:

Major Hopkirk, E.A.A.M.C.: "Ethmoids and sphenoids normal, doubtful opacity of right frontal."

Three days later the eye was worse and the patient complained of pain over the right side of the vertex of the skull and in the right upper teeth. No oedema or proptosis of eye. Two days later—on July 30—there was pyrexia; blood slides were taken for malaria, but were negative. On July 31, the patient complained of a watery discharge from his nose. There was a tenderness on pressure over the right supra-orbital notch.

Dental report by Major E. D. Stanhope (A.D. Corps): "There is no dental cause which might give rise to a reflex pain."

August 12, still complains of pain at inner angle of the right eye and nose, also along zygoma on right side of face. Injection of eye persists. In view of the long persistence of the condition and the lack of any specific indication for treatment it was decided to try the effect of a nerve block. Accordingly 2 c.c. of 3% novotoc were injected at a distance of 2 cm. from the skin, in the middle of the medial wall of the orbit. Three days later it was noted that the eye was much improved, and the patient said it felt better. By August 19 the limbal injection and the sweating were almost gone, and ten days later completely so. He was kept under observation for a further fortnight and then discharged. No recurrence took place.

Literature.—This condition was first described (1930) by Charlin of Santiago, Chile, and elaborated in subsequent papers (1931, 1932, 1936, 1937). The essential features he describes as unilateral rhinitis, pain in the inner angle of the eye, on the side of the tip of the nose and near its root, often accompanied by affection of the anterior part of the eye. "Syndromes frustes" may occur (1931) as is also pointed out by Mangabeira-Albernaz (1939) who believed elevation of ocular tension might occur. Halbron (1936) states that intermediate types make it difficult to distinguish between Charlin's and the "vacuum sinus" syndromes. He explains Charlin's syndrome by a vasodilatation of the anterior ethmoidal artery. The differential diagnosis (from Sluder's syndrome) is discussed by Laskiewicz (1940) and Solonitzky (1936). The aetiological factor is discussed in Charlin's papers—many he thought due to an "épine irritative" in the nose—such as an ethmoiditis, or hypertrophy of the inferior turbinate, stimulation of which caused congestion of the tunnel of the nasal nerve. There were, however, other cases which did not have such a local cause and he found as causes syphilis, diabetes and dental sepsis. The mere performance of the Mantoux test seemed sufficient to cure two cases presumably of allergy to tuberculo-protein.

Treatment was by tamponage of the nose with cocaine and adrenaline (Charlin, Dejean and Artieres, Solonitzky) or directed towards the aetiology in the event of a specific cause being found. The case of Isava (1931) treated by effleurage of a corneal ulcer does not seem to me definitely identified with the syndrome.

Diagnosis.—The differential diagnosis from affections of the pterygo-palatine ganglion may be tabulated thus:

	Syndrome of nasal nerve	Syndrome of pterygo-palatine ganglion
Nasal inflammation	Ant. part inf. concha	Post part middle concha
Relief by coc. and adr.	Applied to ant. part of nasal cavity	Applied to regio gangli. pterygo palat.
Pain	Eye and orbit	Eye and orbit
Anatomical changes	Iritis or keratitis	No anatomical changes in the eye
Hydrophobia	Yes	Yes
Hyperaesthesia and	Cuts of nostrils, forehead and	Not on skin of nose
Herpetic eruption	nose	

DISCUSSION

The anatomical basis of this syndrome is interesting, and can be followed in detail in any textbook of anatomy. Only the most important points are discussed here. The diagram (fig. 2) adapted from Duke-Elder (1932) shows the cutaneous distribution of the terminal branches of the 5th nerve. Areas of pain or tenderness in this case are marked with a cross. From a consideration of the sequence of events it would seem that the naso-ciliary nerve was first involved—branches to the iris and to the skin at the tip of the nose. Under ordinary treatment this improved until on July 22, a relapse occurred, followed by spread of the pain to the scalp (supra-orbital N.), inner canthus (infra-trochlear N.), and right upper teeth (infra-orbital N.). Discharge from the nose was first noted on July 30 and later pain along the zygoma (zygomatico-facial N.).

FIG. 1.

FIG. 2.

FIG. 1.—Photograph of patient showing beads of perspiration on right side of tip of nose and right blepharospasm.
FIG. 2.—Cutaneous distribution of maxillary and ophthalmic divisions of trigeminal (after Zander). Painful spots marked with a cross and affected nervous distributions shaded.

What is the basis of this phenomenon? The autonomic responses of sweating and flushing are presumably axon reflexes (Lewis, 1927). The behaviour of the obscure iritis suggests that it also is of reflex origin, and that somewhere in the pathway of the naso-ciliary nerve lies the cause. It was thought that an ethmoiditis might be the explanation, but in view of the negative X-ray, the rhinologist advised against interference. The frontal sinus is of course supplied by twigs from the supra-orbital nerve, but this did not come into the picture until later. The literature of this condition was not at the time available. However, the theories of Leriche (1939) suggested that blocking of the painful stimuli might bring relief, and an injection of novotox was made over the region of the anterior ethmoidal foramen. This apparently resulted in resolution of the condition in the same period as the cases treated by Charlin (1930) and Solonitzky (1936).

SUMMARY

A case is described of sweating of the tip of the nose associated with iritis and various reflex pains, all strictly unilateral. It is considered that this was a case of Charlin's syndrome, and an alternative form of treatment is described.

Mr. Lionel Green asked whether it might not be a case of herpetic iritis. In this condition the ala of the nose on one side often is similarly involved.

Dr. A. E. Gormaz said that congestion of the nasal mucosa was a very common sign indeed of commencing jaundice. He added that Professor Charlin died in August of last year.

Major Taylor replied that he believed it was a reflex iritis. He did not consider that it connoted any special ætiology. It was only what he considered an axon reflex and might be caused by any change in the distribution of the nerve.

With regard to congestion of the nasal mucosa, he was not a rhino-laryngologist and he had to depend on the opinions of his colleagues. There was definitely rhinorrhœa, but he did not know whether there was congestion.

Section of Anæsthetics

President—GEORGE EDWARDS, M.R.C.S., D.A.

[January 4, 1946]

Anæsthesia for Ear, Nose and Throat Surgery.

By WILLIAM W. MUSHIN, M.B., D.A.

EAR, nose and throat operations are made safe or dangerous, easy or difficult, by the anæsthetist. It is a fact that patients still die during and after tonsillectomy from asphyxia caused by a blood clot in the trachea. They die of respiratory obstruction during mastoid operations in a dark theatre. They die of shock and anæmia after laryngectomy, because the surgeon lacked a tranquil, hæmostatic operation area. Yet few of the operations commonly performed in an E.N.T. department should by themselves endanger life.

All the operations performed by the E.N.T. surgeon can be done efficiently under general anæsthesia; and this is the common practice in this country. There is, however, a growing interest in regional anæsthesia for these operations not, as on the Continent forty years ago, because the standard of general anæsthesia was poor, but because it is believed that for certain operations local anæsthesia has virtues not found in any other method. I myself believe this to be so. I feel that E.N.T. operations like those elsewhere in the body fall into three groups. First, those for which local anæsthesia alone cannot be used with complete success. Examples are mastoid operations and, generally speaking, operations on children. In the second group are those operations like tonsillectomy in which the use of a particular method makes little difference to the success of the operation. The patient's wishes are here the determining factor. The last group is a most important one, since it includes not only everyday operations like the Caldwell-Luc, but the more rare life-saving operations like laryngectomy. Here local anæsthesia makes the operation easier and more likely to be successful, and in the case of operations like laryngectomy may affect the chances of survival.

Since both general and local anæsthesia have their place for ear, nose and throat cases, I propose to deal first in general terms with some of the qualities which are possessed by safe and efficient general anæsthesia and then since it is the more novel method in this country, to deal in a little more detail with local anæsthesia.

Safety.—It should hardly be necessary to stress before a Section of Anæsthetics that the patient's life should not be endangered by the anæsthetic. Not so long ago, at a meeting of this Section, it was seriously put forward from the body of the hall that a child of 5, who was to have its tonsils guillotined, should be given a cocktail anæsthetic

FIG. 1.

Mr. Lionel Green asked whether it might not be a case of herpetic iritis. In this condition the ala of the nose on one side often is similarly involved.

Dr. A. E. Gormaz said that congestion of the nasal mucosa was a very common sign indeed of commencing jaundice. He added that Professor Charlin died in August of last year.

Major Taylor replied that he believed it was a reflex iritis. He did not consider that it connoted any special aetiology. It was only what he considered an axon reflex and might be caused by any change in the distribution of the nerve.

With regard to congestion of the nasal mucosa, he was not a rhino-laryngologist and he had to depend on the opinions of his colleagues. There was definitely rhinorrhoea, but he did not know whether there was congestion.

a diseased internal jugular had just been exposed prior to its ligation. The patient coughed. The vein swelled to the size of a small hen's egg and might have ruptured had not prompt pressure been made by the surgeon.

Hæmostasis.—The E.N.T. surgeon works on tiny structures through small holes. Both the bone he works on and the mucous membrane covering it, are exceptionally vascular. It is no exaggeration that the success or failure of these operations depends very much on whether he can see what he is doing. Even the patient's life may depend on good hæmostasis in the operation wound. I know of patients who have ultimately died because of injury to the dura or lateral sinus lying at the bottom of a mastoid cavity full of blood.

In fact most of the important advances in anæsthesia for E.N.T. operations have been in the direction of making the field of operation more bloodless. Some operations, like the fenestration for otosclerosis, literally cannot be done at all unless the field is virtually dry.

Here are some of the commoner causes which are responsible for a bloody operating field. Their correction is the duty of the anæsthetist: (1) Respiratory obstruction. (2) Straining due to active reflexes. (3) Anoxia. (4) Obstruction to the venous return from the head: (a) tight bands constricting the veins of the neck; (b) faulty position of the head.

The last-mentioned is of particular importance. Good venous drainage of the head and neck cannot take place unless there is an unobstructed venous pathway between the head and the heart. Gravity should be enlisted to help this drainage rather than to hinder it; whenever possible the patient's head should not only be in a natural line with the shoulders but slightly elevated. It may be that the notably dry field obtainable with local anæsthesia for tonsillectomy is partly due to the patient sitting upright. Compare this with the unnaturally extended position of the head commonly adopted for this operation under general anæsthesia. As an example of how the veins of the neck may be constricted, the webbing strap holding the Guy's pattern jack, takes first place.

Prevention of aspiration.—The last of the points bound up with safety is the prevention of aspiration of blood, bits of tonsil or swabs. Under general anæsthesia for operations where this may occur, the airway is kept patent and aspiration prevented by an endotracheal tube; the space between the tube and trachea occluded by a cuff or by gauze packing. Two of the many "don'ts" concerning endotracheal tubes in general are worth repeating here: (1) Don't use a tube unless it is essential; (2) don't use a tube of inadequate bore.

A tube is essential only if without it foreign matter may be inspired or the airway become occluded. To a gathering such as this, this remark savours of the obvious. There is no doubt that endotracheal tubes are often used unnecessarily in this country to the patient's detriment. In my opinion tonsil and mastoid operations in young children do not indicate an endotracheal tube; nor do the majority of mastoid operations in adults. Insufflation of ether vapour into the pharynx is adequate for these operations.

An endotracheal tube has its uses and abuses. Its use for mastoidectomy comes under the latter heading since real indications for this procedure must be few and far between. Apart from the patient with the short fat neck, almost the only justification is an anæsthetist tired at the end of a busy day or one incompetent to maintain an airway by more simple means. I have seen deep anæsthesia induced not for the performance of the operation, but so that an endotracheal tube will be tolerated and this to a patient gravely ill with pneumonia. The fact that most patients survive this insult does not justify its use as a routine.

Using a small endotracheal tube is equivalent to obstructing the patient's airway. Not only is the patient made fatigued and anoxic but the veins of his head become congested, resulting in increased oozing in the wound. If the patient has incipient right-sided heart failure, or the inadequate airway is maintained for a long time, pulmonary oedema may occur.

Following a throat or nose operation under general anæsthesia, the patient is not out of danger until he has recovered his reflexes. The unconscious patient who has just had such an operation needs careful and skilled supervision if he is to avoid grave risk. We are still not free of the tragedy of the patient who is found dead in bed of tonsillectomy. At post-mortem a clot of blood is found obstructing the larynx or bronchi. It is not always possible to send the patient back to bed with active reflexes, and

of rectal avertin, endotracheal tube, nitrous oxide and "puffs of cyclopropane." All this to spare it the ordeal of ether for two minutes. Unfortunately this discussion was never published and this interesting suggestion has not been recorded.

For some years before the war it was common, in anæsthetic literature, to link safety and good results with choice of agent. We have rather preached that safety lies with the anæsthetist and his knowledge of basic principles than on the choice of any particular agent. That this point of view is not confined to the backwaters of the Thames is indicated by the following quotation from a recent paper by Dr. Ralph Waters [1]:

"For each patient who has died from postoperative pneumonia due to irritation of his lungs with the vapor of ether, dozens have died from pneumonia following mechanical obstruction to their air passages. For each patient whose heart has stopped during anæsthesia because of drug effect on the autonomic mechanism which controls it, the hearts of dozens of patients have stopped because the larynx was flooded with vomitus. Perhaps we ought to worry more about the careful supervision of the breathing of our patients and less about our choice of drugs to prevent pain; more about our own personal knowledge and skill with a particular agent or method and less about how someone else says he gets the best results."

Of the general anæsthetic agents, ether is still pre-eminently the one of choice for ear, nose and throat operations—the explosion hazard excepted.

Well-meaning attempts to avoid ether in order to save the patient from theoretical or hypothetical disadvantages of this agent are only made at some cost. For example, nitrous oxide and oxygen, unless reinforced with powerful doses of sedatives, themselves involving some risk of a prolonged depression of the cough reflex, only too often result in a patient who tries to pluck his endotracheal tube out of his nose. If anæsthesia is deepened by reducing the oxygen, we are faced with a patient whose circulation is impeded by asphyxia. The resultant oozing and obscuration of the operative field mitigates against the success of the operation.

Pentothal has but limited use as the main anæsthetic for these operations. It does not as a rule subdue the laryngeal reflexes until it subdues the respiratory ones. Effective cocaineization is necessary, therefore, before intubation or other operations on the larynx can be performed, and cocaine itself is known to be not without its hazards. The prolonged recovery period common after large doses of pentothal, constitutes a greatly increased risk after these operations. Cyclopropane presents the manifold difficulties of maintaining a gas-tight circuit. Trilene is efficient enough but its pharmacology is still being actively investigated and its place in anæsthesia is by no means clear. In my opinion, only when there is danger of explosion and a general anæsthetic is still indicated, should ether be displaced from its premier position as the general anæsthetic for ear, nose and throat operations.

Equipment for resuscitation should always be present and ready for use in an ear, nose and throat theatre, above all places. The two pieces of apparatus I will not do without are a suction apparatus and a means of inflating the patient's lungs. Both of these save lives.

A convenient non-electric portable sucker is that devised by my colleagues Saher and Salt [2]. Any compressed gas can be used with the injector device which entrains air from a bottle connected by tubing to a sucker end. A foot control leaves the anæsthetist's hands free. There are numerous devices by means of which the patient's lungs may be inflated. When these are not to hand, the anæsthetist's own breath blown into his patient's lungs is as good a resuscitant now as it was in biblical times.

Immobility.—Immobility on the part of the patient is essential for safety in E.N.T. operations. I have seen tonsils taken out under gas and oxygen while the patient was struggling, coughing and gagging, and the surgeon's view completely obscured. The danger of aspiration of blood, tonsil or swabs is very great in such a case. In this particular instance, had the anæsthetist but renounced his antagonism to ether, tranquillity could have been achieved at little cost. The patient who strains or coughs raises his intrapulmonary pressure. This is reflected in a rise of pressure in the pulmonary artery, the right side of the heart and the venous system generally. A previously dry operation field becomes filled with blood. I shall have more to say about the undesirability of bleeding during these operations.

I need hardly stress the necessity of immobility during any operation. In delicate operations on the head and neck, a cough may mean a tragedy. I recall a case in which

a diseased internal jugular had just been exposed prior to its ligation. The patient coughed. The vein swelled to the size of a small hen's egg and might have ruptured had not prompt pressure been made by the surgeon.

Hæmostasis.—The E.N.T. surgeon works on tiny structures through small holes. Both the bone he works on and the mucous membrane covering it, are exceptionally vascular. It is no exaggeration that the success or failure of these operations depends very much on whether he can see what he is doing. Even the patient's life may depend on good hæmostasis in the operation wound. I know of patients who have ultimately died because of injury to the dura or lateral sinus lying at the bottom of a mastoid cavity full of blood.

In fact most of the important advances in anæsthesia for E.N.T. operations have been in the direction of making the field of operation more bloodless. Some operations, like the fenestration for otosclerosis, literally cannot be done at all unless the field is virtually dry.

Here are some of the commoner causes which are responsible for a bloody operating field. Their correction is the duty of the anæsthetist: (1) Respiratory obstruction. (2) Straining due to active reflexes. (3) Anoxia. (4) Obstruction to the venous return from the head: (a) tight bands constricting the veins of the neck; (b) faulty position of the head.

The last-mentioned is of particular importance. Good venous drainage of the head and neck cannot take place unless there is an unobstructed venous pathway between the head and the heart. Gravity should be enlisted to help this drainage rather than to hinder it; whenever possible the patient's head should not only be in a natural line with the shoulders but slightly elevated. It may be that the notably dry field obtainable with local anæsthesia for tonsillectomy is partly due to the patient sitting upright. Compare this with the unnaturally extended position of the head commonly adopted for this operation under general anæsthesia. As an example of how the veins of the neck may be constricted, the webbing strap holding the Guy's pattern jack, takes first place.

Prevention of aspiration.—The last of the points bound up with safety is the prevention of aspiration of blood, bits of tonsil or swabs. Under general anæsthesia for operations where this may occur, the airway is kept patent and aspiration prevented by an endotracheal tube; the space between the tube and trachea occluded by a cuff or by gauze packing. Two of the many "don't's" concerning endotracheal tubes in general are worth repeating here: (1) Don't use a tube unless it is essential; (2) don't use a tube of inadequate bore.

A tube is essential only if without it foreign matter may be inspired or the airway become occluded. To a gathering such as this, this remark savours of the obvious. There is no doubt that endotracheal tubes are often used unnecessarily in this country to the patient's detriment. In my opinion tonsil and mastoid operations in young children do not indicate an endotracheal tube; nor do the majority of mastoid operations in adults. Insufflation of ether vapour into the pharynx is adequate for these operations.

An endotracheal tube has its uses and abuses. Its use for mastoidectomy comes under the latter heading since real indications for this procedure must be few and far between. Apart from the patient with the short fat neck, almost the only justification is an anæsthetist tired at the end of a busy day or one incompetent to maintain an airway by more simple means. I have seen deep anæsthesia induced not for the performance of the operation, but so that an endotracheal tube will be tolerated and this to a patient gravely ill with pneumonia. The fact that most patients survive this insult does not justify its use as a routine.

Using a small endotracheal tube is equivalent to obstructing the patient's airway. Not only is the patient made fatigued and anoxic but the veins of his head become congested, resulting in increased oozing in the wound. If the patient has incipient right-sided heart failure, or the inadequate airway is maintained for a long time, pulmonary œdema may occur.

Following a throat or nose operation under general anæsthesia, the patient is not out of danger until he has recovered his reflexes. The unconscious patient who has just had such an operation needs careful and skilled supervision if he is to avoid grave risk. We are still not free of the tragedy of the patient who is found dead in bed of tonsillectomy. At post-mortem a clot of blood is found obstructing the larynx or bronchi. It is not always possible to send the patient back to bed with active reflexes, and

inadequate nursing supervision, only too common in the present shortage of nurses, exposes the patient to risks of respiratory obstruction, inhaling blood, and even of dying. It is therefore the duty of the anaesthetist to see that nurses or orderlies know how to look after an unconscious patient.

In striving to make anaesthesia for these operations safer, the operating conditions better for the surgeon, and the convalescence quicker and pleasanter for the patient, we have continually asked ourselves the following questions: (1) Is an endotracheal tube essential? (2) Can the operating field be made more bloodless? (3) Can the patient retain his own essential reflexes throughout, so that he can guard himself from the dangers of aspirations? (4) Can the immediate post-operative period be made safer and require little supervision?

The answer to these, we feel, lies in the adoption of local anaesthesia whenever possible.

I would like, here, to pay a tribute to Mr. T. B. Layton, Senior E.N.T. Surgeon at Guy's Hospital for first stimulating me to take an interest in this form of anaesthesia. Local anaesthesia is old, but local anaesthesia without vocal anaesthesia for these operations was something new. I learnt from him two secrets of successful local anaesthesia—the importance of the right atmosphere in the ward and theatre and the importance of gentleness and patience on the part of the anaesthetist and surgeon.

The advantages of local anaesthesia are many, the three main ones in the case of E.N.T. operations undoubtedly being the haemostatic operation area, the immunity from aspiration of blood, and the incomparably pleasanter and trouble-free convalescence. To this I would add one more—the absence of tubes and other foreign bodies in the surgeon's field (I have always winced at the endotracheal tube lying in the cancerous larynx).

I think it would be well at this point if I were to define what I mean by local anaesthesia. I mean perfect and absolute anaesthesia of the whole operation area. I mean an operation by a surgeon who is used to the method and who can operate in silence without strain. I mean a ward and theatre where every doctor, nurse, porter, and even ward maid regards local anaesthesia as a routine method and where every patient feels that whatever form of anaesthesia is used it will be a well-considered choice. He may spontaneously express a wish to be awake or asleep, and if, as I have said, it makes no difference to the surgeon or anaesthetist, his request is indulged. Other patients are not questioned regarding anaesthesia, thereby avoiding the embarrassing necessity on the part of the patient of making a decision without the knowledge on which to base it. Should the anaesthetist decide on local anaesthesia, no apologetic explanations are made to the patient since none are needed. Any disparaging reference to local anaesthesia in the patient's hearing undermines his confidence in the method without which the smooth course of the anaesthetic is jeopardized. A visit to a centre where the advantages of local anaesthesia are exploited will convince one that mere technique is not enough; the correct atmosphere is essential. The substitution of nerve blocks for inhalation anaesthesia, by itself will not bring success.

In this general review I have neither the desire nor the time to describe the technical details of all the blocks used for E.N.T. surgery. I propose to outline briefly the method as used for two typical operations, one on the maxillary antrum and the other on the larynx. My intention is to demonstrate that the blocks are not difficult if they are backed by a knowledge of the relevant anatomy. I personally consider it a waste of time to try to teach local anaesthesia unless the anatomical details are thoroughly understood and can be visualized by the student. The proper place to learn local anaesthesia technique is not in the lecture room but in the post-mortem room, and later in the operating theatre, with the guidance of an experienced anaesthetist.

With regard to premedication before local anaesthesia, my only comment here is that when the confident patient is in the hands of the expert anaesthetist—common enough after all in dental practice—he should need little or none. Gentleness and consideration are more important than morphia, although this drug should be used as freely as the patient's and the surgeon's temperament demand.

Here followed brief descriptions of the technique and results of bilateral vagus nerve block and maxillary nerve block. Vagus nerve block for major laryngeal and oesophageal surgery has already been described in the *Proceedings* [3].

Maxillary nerve block is produced by passing a needle through the skin of the face in front of the ramus of the mandible and below the zygoma into the sphenopalatine fossa. Injection here produces anæsthesia of the maxillary nerve and the sphenopalatine ganglion and their branches.

Mr. R. G. Macbeth: The operative techniques of otolaryngology are not necessarily the most difficult, but because many of them involve the vital airways, they call for special methods. Similarly, because the surgeon and anæsthetist are both claiming those airways, the anæsthesia presents special difficulties. Unless both parties are reasonably skilled, each may hamper the activities of the other. I believe that the operations of my specialty offer the general anæsthetist some of his greatest difficulties; and conversely, if the anæsthetist is less than expert, the surgeon carries out his share of the work less than well.

On the continent of Europe methods employing local and regional anæsthesia are most usual even for mastoid surgery, and it is only now that there is a realization that skilled general anæsthesia is sometimes a help to the surgeon. It is astonishing to our eyes to find an article in a recent Scandinavian journal in which the author triumphantly describes 500 tonsillectomies under general anæsthesia. The anæsthetic method noted and the apparatus illustrated would not commend themselves to you as very advanced, but the continental trend towards general anæsthesia, and the British trend towards regional, surely represent two facets of the same mental attitude, namely a healthy dissatisfaction with the *status quo*.

The popularity of general anæsthesia for E.N.T. operations in Great Britain is probably not unconnected with the facts that this country is the birthplace of practical general anæsthesia, and that the specialists in this field have for many years been really skilled. In 1936 there was a combined meeting of this Section with that of Laryngology. At that meeting an eminent anæsthetist, noted for his skill at endotracheal work announced that if he were having his tonsils removed again, he would choose a local anæsthetic. It was there, too, that Mr. Layton enunciated "the principle of the guarded larynx". He emphasized that this is the keystone of the edifice of safety and success in this work. While accepting that principle, I would agree with Dr. Mushin in going a long way further than that in my interpretation of the contribution I would expect of the anæsthetist to the whole of the operation.

I am completely in agreement that the anæsthetist can and should take a big share in the achievement of immobility and of hæmostasis. (What a joy to the ear of the otolaryngologist it is to hear an anæsthetist confess that anoxia tends to produce oozing, rather than proclaim loftily that I am merely noticing the blood more because it is dark in colour!) I share his view, too, about tubes placed unnecessarily in the larynx of anybody, and especially in that of a child. Jackson has taught us that the sub-glottic cellular tissues of children are particularly easily injured. His dictum that a rigid or semi-rigid tube should remain in a child's larynx for the shortest possible time, deserves the greatest respect. Again, the patient with acute mastoiditis usually has a concomitant upper and lower respiratory infection and in such circumstances a tube passed into the larynx and trachea is likely to lead to trouble below the cords.

I also wish to break a lance in condemnation of pentothal, where this is used as the sole anæsthetic agent in nose and throat operations. If you give enough to get all the relaxation we may need, I am convinced that recovery may be delayed, and aspiration becomes a real danger. If you use local anæsthesia and give the patient just enough pentothal to make him drowsy, I have no quarrel with that; but I am most distrustful when a small nose or throat operation is proposed and somebody says: "All we want is a few cubic centimetres of pentothal". I have said it myself before now, and it has not worked.

I take the view that whether the anæsthesia be general or local, it is the job of the anæsthetist to induce it and to maintain it. The method to be employed in any one case should not be dictated by either of us singly, and least of all by the patient; but any of the three parties should be ready to compromise to suit particular circumstances.

As a pupil of V. E. Negus, I was early introduced to the value of local anæsthesia in some operations on adults. But it does demand of the anæsthetist familiarity with the anatomy of the parts to be prepared for operation.

There are two more advantages of local anæsthesia in otolaryngology: (1) It puts a premium upon gentle and precise operating, and therefore stimulates a good technique. (2) The operating time is shortened remarkably because of the diminished oozing, that bugbear of the otolaryngologist. In this connexion I am not pleading that speed of operating is an end in itself, but other things being equal, it is surely an advantage.

It has been stressed that a quiet and orderly environment is essential. If the surgeon is a querulous type, who habitually has his whole theatre staff in a state of nervous tension, or one who gives way to sudden bursts of vocal violence, the patient had better have a general anæsthetic.

Premedication.—If the part has been properly anæsthetized then the operation is painless, and I deprecate whole-heartedly the giving of large quantities of morphia to cover up deficiencies of technique. But I think that enough premedication should be given to blunt the minor discomfort of the application of the local anæsthetic, to allay the patient's natural apprehension, and to diminish his appreciation of the incidental discomforts inseparable from lying or sitting on an operating table. After all the patient's environment lies partly within himself.

I prefer local anæsthesia in the nose and throat operations I am called upon to do, mainly because at all stages the patients are physically so well. It is common, I find, for patients who have had a tonsillectomy or a Caldwell-Luc operation under local anæsthesia, to start reading a novel on their return to bed, and usual for them to take a full meal two to three hours later. These people are not called upon to recover from the intoxication of a general anæsthetic (at best a bad hang-over), nor from the gastro-enteritis due to much swallowed blood; so that their recuperation is accelerated and they are fit to leave hospital several days sooner than they would after the same operation performed under general anæsthesia.

Patients often dread not the operation but the anæsthetic; and how relieved they often are to learn that they need not be put to sleep. If any of our own nurses or students need a tonsillectomy we find that about 75% choose a local rather than a general anæsthetic. These people have mostly seen the operation done under both methods and their choice is, I feel, significant.

Dr. Mushin has made special reference to the Caldwell-Luc type of antrostomy and to laryngectomy. Many surgeons now think the former a better operation than the simple intranasal antrostomy in most cases, and consequently anæsthetists will encounter it more often. I would strongly commend the method described by the reader. If it be objected that the use of a hammer and chisel by the surgeon must be very unpleasant for the conscious patient, I would agree; and hasten to add that the use of a dental burr obviates this.

Various technical factors have made laryngectomy an operation which can now be recommended in the confidence that the outcome is likely to be successful; whereas a few years ago that operation had a mortality rate of about 30% in the best hands. Among the factors which have contributed to this pleasing state of affairs, I would place regional anæsthesia very high, and the vagal block has put a polish and smoothness upon the technique which it previously lacked. This is a lengthy operation and when regional block is used, the lack of surgical shock is most striking. I believe that the interruption of the very rich sensory nerve supply achieved by the anæsthetist's needle is largely responsible for this. When general methods are used, either the patient is kept at a deep level throughout or, if he is run light, too many strong afferent impulses get through to the higher centres. Although Crile's theory of shock has been considerably discredited, I feel sure that in the neck, powerful sensory stimuli are best eliminated.

In conclusion, I would say that while I am not fanatically advocating a local technique wherever possible in otolaryngology, the method should be given a fair trial.

Mr. T. B. Layton recounted three of his experiences.

(1) The first was of Professor Hajek in Vienna in 1912. It was remarkable that except for two new principles subsequently introduced there is but little change in technique since that day.

He did his first maxillary sinus operation under local anæsthesia successfully in November 1912. Two attempts at that date at tonsillectomy were not so successful. In one he took them out from a contemporary fellow-student. They came out but the doctor still refers to it when they meet. The other was a partial success, for though only one tonsil came painfully out the student, who was the patient, married the nurse who squeezed his hand.

(2) The second experience was the visit of Dr. Graham Brown of Brisbane to England in 1923, who taught him to inject the second division of the 5th nerve through the mouth, an approach that he had since thought far better than those through the orbit or cheek, but the one described by Dr. Mushin to-day was new to him. It looked very good except that personally he found himself unable to do any of those injections, at which others were so skilled, that involved striking a bit of the bone with the needle, withdrawing it and pushing it forward again in an altered direction. It was Mr. Graham Brown's insistence that encouraged him to stick to local anæsthesia and to persist in the injections.

(3) The third experience was a visit to Amsterdam in 1928 when the visiting association saw Professor Noordenbos remove a larynx under local anæsthesia and he spent a morning watching the Professor do general surgery under the approach that everything should be done under local anæsthesia unless there were some special reason against it. He then became convinced that whatever might be true of the body generally this was the future of nasal surgery.

Professor Noordenbos summed up local anæsthesia by saying: "It is kinder to the patient; but a greater strain upon the surgeon and therefore more worth doing." From this quiet remark arose his present conviction that in operating under local anæsthesia

it is the mental factor rather than the physiological or anatomical that holds first importance. Every stimulus to the thalamus by whatever route from below or from above must be eliminated or reduced to a minimum to gain success.

The idea introduces a new approach to operative surgery. It makes the theatre technique as important as the surgical technique. It will make a similar change in hospital construction. The hospitals throughout the land that those now back from the war will build will need their theatres in a quiet corner of the hospital with padded ceilings, floors and walls so that no sound from without can reach them, and then those within will gain full benefit from this technique which entails not a sound arising within the theatre except the quiet firm voice of the surgeon encouraging the patient and warning him that he is going to do something that will be uncomfortable. This form of "vocal anaesthesia" is an essential part of the technique.

Dr. H. W. Loftus Dale: I have proved the efficacy of the block of the 2nd division of the 5th nerve and the sphenopalatine ganglion in a series of 300 cases, most of which were for Norman Patterson's radical sinus operation and Caldwell-Luc's, using, however, a different approach (see *Proc. R. Soc. Med.*, 1945, 38, 624-626). I can confirm the value of the technique.

I have also used the bilateral vagal block and have been greatly impressed by the complete absence of all respiratory tract reflexes. A marked rise in pulse-rate (70-140) sustained for ten to fifteen minutes was observed. One patient having a bronchoscopy for ? carcinoma of lung complained afterwards of the very unpleasant sensation of not knowing he was breathing, save by hearing his respirations passing through the bronchoscope.

What is the best anaesthetic for bronchoscopy in small children?

Nitrous oxide is inadequate, ether excluded owing to explosion risks, the danger associated with the use of small electric bulbs having been stressed by experts at a meeting of this Section. Trilene cannot be counted on to provide the necessary relaxation and though the number of administrations up to date indicate a much less chance of primary cardiac failure, this risk cannot entirely be excluded.

The dangers of chloroform are accentuated in bronchoscopy since there is the chance of vagal inhibition or ventricular fibrillation due to sympathetic stimulation. It has been pointed out that stimulation of the stellate ganglion in cats under chloroform anaesthesia produces ventricular fibrillations more readily than does injection of adrenaline. I have had some anxiety more than once, notably a case of cardiac arrest after the successful removal of a halfpenny from a small child by means of a coin catcher, which, happily, responded to somewhat energetic restorative measures including inversion.

And children are said to be supersensitive to cocaine.

Mr. A. B. Alexander: W. W. Mushin considers a mastoid operation unsuitable for local anaesthesia. While it is admittedly preferable to perform mastoid operations under general anaesthesia in the majority of cases, the local technique is nevertheless existent and important, and the now revived operation of "fenestration" brings this technique again into the limelight. The impact of the gouge is often unpleasantly felt—a point which Dr. Mushin stressed with regard to the Caldwell-Luc operation—and I have found it useful, and relieving to the patient, to place a piece of thick rubber tubing in the patient's mouth and when using the gouge and hammer to ask him to bite on it firmly.

W. W. Mushin condemns the small bore tube: I find it a useful implement of anaesthesia for the removal of polypi from the cords: its size enables the surgeon to displace it, and to enjoy a free field of operation while at the same time gaining the advantages of an intratracheal, unhurried and well-maintained anaesthetic. The airway is assured by the introduction of the laryngoscope, and I would like to ask Dr. Mushin whether he does not regard this type of anaesthetic as safe, and as worth while continuing.

The regional anaesthesia for the Caldwell-Luc type of operation by nerve block is, in my view, open to one major criticism: i.e. that it is quite unnecessary. Regional anaesthesia does not exempt the surgeon from procuring surface anaesthesia of the nose in addition. This, as Dr. Mushin has pointed out, is due to the fact that not only the second branch of the trigeminal nerve provides sensory innervation of the nasal mucous membrane. Surface anaesthesia of the nose, augmented by novocain infiltration of the canine fossa and surface anaesthesia of the mucous membrane lining the antrum is, by itself, sufficient for the Caldwell-Luc type of operation, and the regional block, while doubtless an impressive performance, can easily be dispensed with.

Premedication I consider to be of great importance in local anaesthesia. I have learnt the value of premedication from Mr. Layton, and would not now care to perform an operation under local anaesthesia without it. In the surgery of the antrum it enables one to keep the patient in a twilight sleep throughout the operation.

As for tonsillectomy under local anaesthesia: during the war I operated on a large number of sailors at the Southern (E.M.S.) Hospital. An Admiralty ruling existed, whereby no sailor was to be made to undergo an operation under local anaesthesia unless he had out of every 10 patients expressed a predilection for local anaesthesia. 4 out of every 10 could, after initial hesitation, be persuaded to have the operation done under local

anæsthesia. The remaining 50% preferred a general anæsthetic under all circumstances. These figures, while different from Mr. Macbeth's, may give a clue as to the proportion of patients we can expect to operate on under local anæsthesia amongst groups of people not attached to a hospital.

Dr. R. W. Cope: The anæsthetic technique for the operation of removal of tonsils and adenoids in children at the Hospital for Sick Children, Gt. Ormond Street is as follows:

The principle of the method has not altered at all since Waugh introduced his operation in 1907. Waugh dissected the tonsils and curetted the adenoids under very deep anæsthesia, which was produced originally by chloroform. The main points of the operation which concern the anæsthetist are these: a small sandbag is placed under the child's shoulders and the head is fully extended so that the occiput only rests on the operating table. The mouth is kept open by the use of Waugh's gag and the tongue is pulled firmly and continuously out of the mouth by an assistant holding a pair of tongue forceps of the Mayo towel clip pattern. These forceps take a good bite of the tongue at least 1 cm. away from the tip. If they are placed in this position then the tongue will suffer no trauma at all, however long the forceps are left in position. The other duty of the assistant's hand which is holding these forceps, is to push upwards, that is, towards the surgeon, on the point of the chin. Failure to do this simple act causes a greater or lesser degree of respiratory obstruction immediately. No Boyle Davis gag is used, and this fact coupled with the deep plane of anæsthesia allows the faucial pillars to be perfectly relaxed throughout the operation.

The anæsthetic vapour, whether it be carried by air from a foot-bellows or by oxygen from a cylinder is insufflated into the mouth by means of a "J"-shaped metal tube. This tube is weighted in its vertical part, while the opposite end curves over the teeth and lies just inside the mouth cavity.

For many years pure chloroform was the anæsthetic agent used, later a change was made to ether and air; now oxygen is used in all the theatres as the vehicle carrying the ether vapour.

Premedication has been used for over twenty-five years. This is just as important as the anæsthetic itself, certainly in the case of children to abolish their natural fears of the mask being put on their faces. By his perseverance and teaching of the importance of this subject, Sington, a late President of this Section, instituted a routine use of paraldehyde *per rectum* for these and other cases. This practice was most gladly welcomed by the patients and the anæsthetist, and held a well-deserved popularity for many years. But now the method for producing the same state of quiet sleep has changed, and some form of oral barbiturate has taken the place of paraldehyde. At the present time nembutal 0.6 grain per stone of body-weight seems the most popular drug, although just before the war I was using secconal 0.75 grain per stone with what I thought were better results than with the former preparation.

The foregoing remarks briefly show how little this particular operation and anæsthetic technique has changed since its introduction so many years ago. At the present time I am told it is carried out an average of 35 times each week at Gt. Ormond Street.

Section of Otology

President—A. J. WRIGHT, F.R.C.S.

[November 2, 1945]

Cochlear Deafness¹

PRESIDENT'S ADDRESS

By A. J. WRIGHT, F.R.C.S.(Bristol).

As a result of clinical and pathological research carried out during the last ten years many of us have come to regard Ménière's disease as an entity. It is common ground that the auditory disturbance in the form of deafness, tinnitus or both precedes the vertigo in the majority of cases and often by a long period. We therefore must arrive at the conclusion that we otologists see a large number of cases of perceptive deafness without vertigo which nevertheless belong to the entity of Ménière's disease. I think there is also little doubt that this group of cases of perceptive deafness includes the majority of those the nature of which has been uncertain in the past.

In 1937 I read a paper before this Section under the title of Aural Vertigo in which was included a summary of what seemed to me to be the clinical picture of the cochlear element of Ménière's disease (Wright, 1937). Since that date similar clinical findings have also been published, notably by Crowe (1938), Cawthorne, Fitzgerald and Hallpike (1942) and Altmann and Fowler (1943). In all these descriptions, however, the auditory picture has been included as part of, and rather overshadowed by, the vestibular element.

I feel therefore that I might possibly make a useful contribution to-day by endeavouring to draw a more detailed picture of this disease as we see it in the absence of vertigo.

An additional reason for making this attempt is that avoidable errors in diagnosis are not uncommon. Thus I find that many cases referred to me have been previously treated as cases of middle-ear defect with repeated inflation, &c. The reason for this is understandable in that superficially the picture presented does suggest a derangement of the middle ear.

I propose to deal with each symptom in turn and then briefly bring these together into one picture:

Sex and age.—There is no significant incidence in regard to either sex. While this type of cochlear deafness is most commonly met with in adult life cases occasionally occur in children.

Onset.—The earliest symptom complained of is usually tinnitus and this may exist for some considerable period before any appreciable defect in hearing is noticed.

Sometimes the history is given of a dramatically sudden onset with deafness and tinnitus both of which may be of high degree. Such an onset may be described as being accompanied by the sensation of a blow on the side of the head or of a loud bang in the ear. This occurrence would seem to suggest a vascular origin, such as a hæmorrhage but from a careful consideration of the subsequent course of the complaint, in which a rapid return of the hearing may be noted, I am satisfied that these cases do conform to the usual picture.

¹ Under a grant from the Nuffield Trust.

anæsthesia. The remaining 50% preferred a general anæsthetic under all circumstances. These figures, while different from Mr. Macbeth's, may give a clue as to the proportion of patients we can expect to operate on under local anæsthesia amongst groups of people not attached to a hospital.

Dr. R. W. Cope: The anæsthetic technique for the operation of removal of tonsils and adenoids in children at the Hospital for Sick Children, Gt. Ormond Street is as follows:

The principle of the method has not altered at all since Waugh introduced his operation in 1907. Waugh dissected the tonsils and curetted the adenoids under very deep anæsthesia, which was produced originally by chloroform. The main points of the operation which concern the anæsthetist are these: a small sandbag is placed under the child's shoulders and the head is fully extended so that the occiput only rests on the operating table. The mouth is kept open by the use of Waugh's gag and the tongue is pulled firmly and continuously out of the mouth by an assistant holding a pair of tongue forceps of the Mayo towel clip pattern. These forceps take a good bite of the tongue at least 1 cm. away from the tip. If they are placed in this position then the tongue will suffer no trauma at all, however long the forceps are left in position. The other duty of the assistant's hand which is holding these forceps, is to push upwards, that is, towards the surgeon, on the point of the chin. Failure to do this simple act causes a greater or lesser degree of respiratory obstruction immediately. No Boyle Davis gag is used, and this fact coupled with the deep plane of anæsthesia allows the faucial pillars to be perfectly relaxed throughout the operation.

The anæsthetic vapour, whether it be carried by air from a foot-bellows or by oxygen from a cylinder is insufflated into the mouth by means of a "J"-shaped metal tube. This tube is weighted in its vertical part, while the opposite end curves over the teeth and lies just inside the mouth cavity.

For many years pure chloroform was the anæsthetic agent used, later a change was made to ether and air; now oxygen is used in all the theatres as the vehicle carrying the ether vapour.

Premedication has been used for over twenty-five years. This is just as important as the anæsthetic itself, certainly in the case of children to abolish their natural fears of the mask being put on their faces. By his perseverance and teaching of the importance of this subject, *Sington*, a late President of this Section, instituted a routine use of paraldehyde *per rectum* for these and other cases. This practice was most gladly welcomed by the patients and the anæsthetist, and held a well-deserved popularity for many years. But now the method for producing the same state of quiet sleep has changed, and some form of oral barbiturate has taken the place of paraldehyde. At the present time nembufal 0.6 grain per stone of body-weight seems the most popular drug, although just before the war I was using secconal 0.75 grain per stone with what I thought were better results than with the former preparation.

The foregoing remarks briefly show how little this particular operation and anæsthetic technique has changed since its introduction so many years ago. At the present time I am told it is carried out an average of 35 times each week at Gt. Ormond Street.

Hyperacusis.—I have on one occasion recorded what was apparently a true hyperacusis early in the disease, i.e. an audiogram curve above the normal level from an ear in which there was a complaint of tinnitus and hypersensitiveness. More frequently the complaint is of the unpleasantness or even pain associated with loud sounds. Such sensitiveness is found both in the early and late stages of the disease. Thus the patient, although very deaf, may complain bitterly of the discomfort produced by speech when loud enough to be audible.

Tinnitus.—This is the most constant symptom and not infrequently the earliest. It was absent, in my experience, in only 4% of cases but these were otherwise typical. Its most striking characteristic as met with in this disease is its variability both in type and intensity. It also shows the same variability in degree as do the deafness and other symptoms. I find in my records some twenty different types described by the patient. Apart from whistling, hissing, buzzing, the noise of machinery and throbbing which form the most common types, the sound of a bubble bursting, a clicking on movement of the head and a buzzing brought on by noise only are noteworthy. I think it is probably in this disease that we meet with the nearest approach to an intolerable tinnitus.

Membrane and middle ear.—In my previous series, some 20% showed old changes in the tympanic membrane or middle ear consisting of scarring, opacity or retraction. In this further series, the figures are almost precisely the same, and, as has already been said, this proportion is such as one finds in cases seen for infection in nose, mouth or throat, but without any labyrinthine disease. Apart from the question of gross disease of the middle ear, I have noted on several occasions the existence of a dilated vessel down the handle of the malleus, and, on one or two occasions, a blush due to hyperæmia of the inner tympanic wall such as one is wont to associate with otosclerosis. I suggest that these findings are not inconsistent with a labyrinthine congestion, and I have been interested to note that Monteiro (1938) has recently recorded the dilatation of this vessel in cases complaining of tinnitus and swimmy sensations in the head.

SUMMARY

The cochlear lesion of Ménière's disease precedes the vestibular in the majority of cases and often for a long period. The clinical picture thus presented is of tinnitus variable in type and degree, with progressive deafness which is usually unilateral. The deafness tends to be variable and is often accompanied by hyperacusis and paracusis. It is perceptive in type but tuning-fork tests are liable to mislead if masking of the better ear is not employed. A sense of fullness in the affected ear is usual and inflation may produce a short-lived improvement in the hearing. These latter findings tend to lead to a mistaken diagnosis of a middle-ear defect.

Mr. F. W. Watkyn-Thomas said that the President deserved thanks for giving an extraordinarily clear picture of a most difficult problem. He found himself, however, in disagreement on certain points. First of all as to the points on which he agreed; he was most grateful for the President's reminder as to the confusion of diagnosis between middle ear and cochlea. Although it had been emphasized abroad, it was still not sufficiently widely recognized in this country that with a perfectly straightforward middle-ear case, such as a blocked Eustachian tube and an impressed membrane, one could get a loss of bone conduction.

On the question of septic foci he had not been very fortunate in his results, but where a septic focus was responsible for a nerve deafness, the removal of that septic focus was a "dramatic success"—but it was either nothing or everything. Curiously enough, he still had to say that his best results had been in cases where the septic focus was dental or abdominal, such as the gall-bladder. He had now seen three dramatic cures of an apparent early Ménière's as the result of a cholecystectomy.

Among the present causes of nerve deafness he was wondering whether they should not include an over-enthusiasm for sulphonamide dosage. It seemed to him that he had seen an increasing number of cases lately, and some of them bore out that suggestion; he quite admitted the possible alternative—in each case the deafness might have been due to the toxic process. In the case of an old lady with general peritonitis who had had a long course of sulphonamide treatment and who showed an enormous increase in her deafness, a pure nerve deafness, it could be said, he thought, with justice, that the increased deafness had nothing to do with the sulphonamides, it had to do with the lowering of resistance and the septic absorption. But this was a thing to remember.

The point on which he was in disagreement with the President was the vascular element in some of these cases. He quite agreed that a large hæmorrhage would be irrecoverable,

Such an occurrence should be expected in that the vestibular symptoms frequently present a similar dramatic onset and resolution. I find that I have noted such a type of onset in some 7% of cases.

A history of trauma as the exciting cause is frequent, as examples of which I would instance the explosion of a firework in a confined space or the exposure of the side of the head to a cold draught during a long motor drive.

Instead of, or in addition to, tinnitus and/or deafness some form of paracusis may be the earliest symptom. On more than one occasion patients have come to me complaining simply of an altered pitch perception in one ear, usually in the high tones. Such a defect, as one would expect, is more likely to be noticed by an individual with a trained musical ear.

Hyperacusis in the form of discomfort in the ear produced by any loud sound is sometimes an initial symptom; but in my experience tinnitus usually accompanies this.

Hearing loss.—The degree of defect ranges from one which is only discovered as a result of careful testing down to a total loss. From the patient's standpoint the deafness is most frequently unilateral although careful testing will often discover a defect in what the patient regards as a perfect ear.

From a clinical standpoint Ménière's disease does not frequently produce a high-grade deafness in both ears—my records showing a figure of 8% in this respect. When it does so it is usually in cases in which the deafness was definitely bilateral in onset. Where the complaint is decidedly unilateral in degree there is a strong probability that the other ear will retain useful hearing in the future.

Type of hearing loss.—This is perceptive but if care be not taken in the interpretation of tuning-fork tests a mistaken diagnosis of a conductive deafness may be made. It must of course be recognized that the cochlear lesion may occur in an ear already the seat of a conductive defect and therefore presenting a mixed type of deafness. Such cases usually present gross evidence of middle-ear abnormality on otoscopy.

Tone loss.—The most usual finding in the early stages is a high tone loss. Later all tones are involved. Occasionally the audiogram presents a spiky picture and an early low tone loss is also sometimes found. There is therefore no typical audiogram in Ménière's disease.

Tuning-fork tests.—Unless these are used with the utmost care they are liable to lead us astray. With a unilateral deafness of pronounced degree Rinne and bone conduction tests will inevitably mislead in the absence of masking of the good ear.

Weber's test may not so frequently lead to error.

Thus I find that I have recorded in some 4% of cases a reference of the fork to the affected ear and in such cases you will sometimes find that the side of reference will vary with the pitch of the fork concerned. The false result in such cases is, I suggest, perhaps due to the abnormality of the sensation produced in the diseased cochlea.

Paracusis.—This is a frequent and often an early symptom but may persist to a late stage when there exists a gross hearing defect. It is most often described as a general distortion and jangling of sounds heard but as already stated may present an orderly picture in which to one of musical ear it is noted that musical notes are sharp or flat as the case may be. Such a change in pitch perception seems to occur at the margin of a tone defect when present. I have noted six cases in which such a condition was investigated in some detail. In these I was interested to find that in all altered pitch perception in high tones was always sharp and in low tones always flat. Two of the six cases presented an altered perception at both the upper and lower ends of the scale and in these also the high tone was sharp and the low tone flat. If this should prove to be a constant observation interesting deductions might be made as to the responsible cochlear change. There would seem to be possibilities of alterations in length, tension and loading in the basilar membrane or other vibrating structure.

Variability in hearing is very frequent and one of the most dramatic features of the disease. Periods of deafness often come on rapidly and disappear as quickly, any associated symptom such as tinnitus often following the same course. So common and suggestive is this variability that I am in the habit of inquiring for it early in the taking of a history. Its presence to a pronounced degree is almost diagnostic.

Sensory phenomena.—The great majority of cases complain of a fullness, numbness or feeling of pressure in the ear. This may sometimes amount to a sensation of pain in the ear or over the mastoid. There may often be headache which may be frontal, occipital, or temporal or even be described as radiating down the neck. Occasionally a sensation of something loose in the ear on movement of the head is noted.

of the ear in these cases must act during the period when the vestibular apparatus had already been formed but the cochlear apparatus had not yet been developed.

There was one annotation to be made. Everybody, he was sure, had seen cases of typical Ménière's disease or attacks in which no disturbance of hearing occurred. These cases were rare, but they did exist. In such cases it was necessary to conclude that this was a different sort of Ménière's as compared with ordinary cases.

He thought also that it would be highly desirable if somebody interested would survey again the whole of the tuning-fork tests in view of the present possibilities of improved acoustic methods. The tuning-fork tests were still based on statements and findings which were made more than sixty years ago. The original Weber test was not really meant as a test. What Weber did was to note the fact that if the tuning-fork was put in the middle line of the skull and one ear closed with the finger, the sound of the note was perceived in the closed ear. The Weber test as well as the Rinne test well deserved to be examined more closely, because no one, so far as he knew, was aware of what difference in hearing power between the two ears must exist in order to produce a Weber result. On the other hand, it might possibly be that the Weber test was so fine a test that it showed lateralization in the cases where no other means of testing the hearing showed anything to be wrong.

As regards Mr. Cawthorne's comments on the Rinne test, he had always been of opinion that in cases with more than a certain amount of hearing defect the Rinne test became unreliable. Not everything was quite clear as yet about the Rinne test. When they began to undertake surgical destruction of the whole labyrinth they found that afterwards, when everything was healed, in many of these cases, with one destroyed labyrinth, the tuning fork was referred to the operated side. There must be something in the acoustic conditions of the bony skull which furnished the reason for this, but as yet it was not understood. The President's explanations, valuable in themselves, might induce further study.

Mr. Ian Robin asked how long one waited in a case of unilateral deafness and tinnitus, before vertigo arose, while making a diagnosis of Ménière's disease. Was it necessary to have tinnitus to diagnose Ménière's? If there were deafness and vertigo without tinnitus could that be put down as Ménière's?

The President, in reply, said that he had intended to present quite a simple little picture of one facet in this very involved and complicated disease. They had described cases of Eustachian obstruction with perceptive deafness, treated them, and all the deafness disappeared. How common was that? So many individuals had said that it occurred that he must accept it, but how often did it occur? He thought it was very rare.

He could not see any reason why there should not be hæmorrhages in the cochlea and thrombosis in a vessel; it would seem inevitable. Twenty years ago he used to write to the doctor and say that that was what he expected had happened, but he thought personally that the general picture showed that the vascular element was not the usual one.

He, the President, thought that Mr. Vlasto had experienced the same condition in a minor degree. When these conditions started in a minor degree they usually remained so, and in Mr. Vlasto's position, if his pipe were a great joy to him, he would continue with it. On the other hand, if there were any dead teeth he should have them out. The "Punch and Judy" sound was quite typical. That type of distortion was the sort of thing that patients told one about, and it was probably diagnostic, and was found only in this type of cochlear deafness.

The President, continuing, said that the prognosis was particularly good, especially in a mild condition which remained mild.

On the question of injury as the first step in a progressive change in the labyrinth he could not tell how often a progressive lesion was found following an injury. He saw a lot of cases with progressive changes in the labyrinth, and in a few of these there was a history of injury.

In reply to Mr. Forster, he had always found that general picture of interstitial œdema and so on rather vague. He remembered that at Copenhagen several patients were shown with classical Ménière's disease and various things were picked out and they were asked whether they were not all abnormal. Frankly he did not think so. He thought the evidence that reducing people's fluid intake did diminish the severity of their symptoms was fairly established. A large number of intelligent observers had produced evidence to that effect. But it had its risks. He saw a man in a nursing home who was getting renal colic because of oxaluria and he had oxaluria because he had Ménière's disease and had stopped drinking; he had been drinking only small quantities for some years. He advised him to drink and to have his teeth out.

On the question of the motor-car and the vertiginous driver, it was hard to say how big was the risk. Probably it varied in each case. His experience had been that there was practically always enough warning to enable the driver to run on to the side of the road and put on the brakes. But there was a very serious legal position over certification, and if the question was put as to whether attacks of giddiness were experienced, it was necessary to say that they must not drive a car. Apart from the legal question, he did not believe that the risk of accident resulting from an attack of vertigo was a very serious one.

He had been asked how long one should wait in a case of defective hearing before deciding that the defect was due to the condition they had been calling Ménière's disease. He would not wait at all. His object had been to present a plea that this could be recognized at the beginning, that one did not have to wait for vertigo, which might never happen, but that the auditory picture was the same one in this stage as it was in the established condition.

but the question of—he did not know whether the phrase was legitimate—an exudative hæmorrhage must be taken into account—the sort of thing one saw occasionally in the terminal branches of a retinal vessel where there was a certain degree of retinitis and apparently some localized hæmorrhage. He had himself noticed this “come and go” of symptoms in some of these cases, but they had not ended up as Ménière's condition, they had ended up in a severe degree of perceptive deafness.

He agreed with the President as to the absence of any typical audiogram in Ménière's.

A further question arose on the reference of the Weber test according to the pitch: he thought this similar to the positive or negative Rinne according to pitch, which was obtained in many cases of otosclerosis.

On the question of hyperacusis, he felt that that would fit in very well with the President's view of a toxicemic condition. If it were a toxic neuritis one would expect an early stage of hyperacusis, just as in many other examples of peripheral neuritis one had an early stage of increased localized sensitivity; tinnitus would fit in very well with that as a form of neuralgia.

Mr. Terence Cawthorne said that the President had made an important reference to paracusis or diplacusis. One of the most characteristic features of perceptive deafness accompanying or preceding Ménière's disease was dislike of loud sounds and particularly of loud high-pitched sounds. It was a very common thing for a patient with Ménière's disease to volunteer the information that he could not bear to listen to music on the wireless, shrill voices or to children. Some sufferers could not have a meal in a restaurant because they found the clatter of knives and forks on the plates unbearable.

Sometimes one was faced with a patient who had very little hearing left and a decision had to be made whether the labyrinth should be destroyed or the vestibular portion of the nerve divided by an intracranial operation in an attempt to save the hearing on the affected side. Given a normal, or almost normal, ear on the sound side, he thought that no patient with Ménière's disease would ever thank the surgeon for leaving him with distorted hearing. On the contrary, he had often found that after a patient had been relieved of his distorted hearing he was once again able to enjoy the everyday noises of civilization.

He entirely agreed with the President that a very characteristic feature of Ménière's disease was the variability of the hearing. He had heard it said on more than one occasion that the perceptive deafness did not get better but always worse; but there was no doubt that in the type of perceptive deafness under discussion variability was the rule.

One important point was the negative Rinne. It was a physical sign of severe unilateral perceptive deafness that a patient could hear the tuning fork better by bone conduction than air conduction on the affected side. He had years ago been caught by this in a rather hurried examination, mistaking a perceptive for a conductive deafness, because of an apparently negative Rinne. In every case of unilateral perceptive deafness of severe intensity there would be a false negative Rinne, as could be shown quite well by masking. It was, he felt, that false negative Rinne which had led to the widespread belief that one of the commonest causes of Ménière's disease was Eustachian obstruction. His own experience was that Eustachian obstruction was very rarely seen in association with Ménière's disease.

Mr. Michael Vlasto said that a personal experience might be of interest. About six months ago he developed a sudden slight nerve deafness on the right side. He had been afraid that it might be a precursory symptom of Ménière's disease. But he had had neither tinnitus nor vertigo. He consulted three colleagues who kindly thoroughly investigated his case which included the puncture lavage of one slightly infected antrum. They had advised his giving up smoking. The most distressing feature of his affection in its earliest stage was a “Punch and Judy” effect of high pitched voices. This feature had now disappeared and his condition was otherwise stationary in spite of a resumption of smoking. Would the President kindly give his views on the possible ill-effect of smoking on his condition, and also as to the prognosis.

Mr. F. McGuckin had long been interested in Eustachian obstruction and, though there might be other causes, he had noted the following: trauma, adenoids, œdema of the torus tubarius, and neoplasm. In no case of proved Eustachian obstruction had there been any complaint of vertigo.

Mr. H. V. Forster said that he would ask Mr. Wright if he was in agreement with the theory held by Mygind and Dederding that certain cases of intermittent inner-ear deafness, associated at times with vestibular vertigo were caused by disturbance of the water metabolism of the body. Had he confidence in their method of treatment by reducing water and salt intake in the diet?

He, Mr. Forster, had personal reasons for believing that such passing attacks of inner-ear depression were associated with temporary loss of hearing for C32, with distortion of the tone of C₅₁₂ and perhaps later with some permanent loss in the higher “frequencies”.

Dr. Hugo Frey said that he found it a very interesting fact that the President was able to show that as a rule the cochlear apparatus showed signs, much earlier than the vestibular apparatus, of approaching Ménière's disease. He thought the explanation of this was that, on the whole, the cochlear apparatus in the human ear must be regarded as belonging to a later period of development. It was known that the lower classes of animals had no cochlear apparatus nor any acoustic perception; also it was found that in congenital deaf-mutes where there was malformation of the inner ear there were, with few exceptions, defects in the cochlear part of the inner ear, but not in the vestibular part. They gave when tested the vestibular reaction but very little or no cochlear reaction, which showed, *inter alia*, that the special factors which might be blamed for the deformity

of the ear in these cases must act during the period when the vestibular apparatus had already been formed but the cochlear apparatus had not yet been developed.

There was one annotation to be made. Everybody, he was sure, had seen cases of typical Ménière's disease or attacks in which no disturbance of hearing occurred. These cases were rare, but they did exist. In such cases it was necessary to conclude that this was a different sort of Ménière's as compared with ordinary cases.

He thought also that it would be highly desirable if somebody interested would survey again the whole of the tuning-fork tests in view of the present possibilities of improved acoustic methods. The tuning-fork tests were still based on statements and findings which were made more than sixty years ago. The original Weber test was not really meant as a test. What Weber did was to note the fact that if the tuning-fork was put in the middle line of the skull and one ear closed with the finger, the sound of the note was perceived in the closed ear. The Weber test as well as the Rinne test well deserved to be examined more closely, because no one, so far as he knew, was aware of what difference in hearing power between the two ears must exist in order to produce a Weber result. On the other hand, it might possibly be that the Weber test was so fine a test that it showed lateralization in the cases where no other means of testing the hearing showed anything to be wrong.

As regards Mr. Cawthorne's comments on the Rinne test, he had always been of opinion that in cases with more than a certain amount of hearing defect the Rinne test became unreliable. Not everything was quite clear as yet about the Rinne test. When they began to undertake surgical destruction of the whole labyrinth they found that afterwards, when everything was healed, in many of these cases, with one destroyed labyrinth, the tuning-fork was referred to the operated side. There must be something in the acoustic conditions of the bony skull which furnished the reason for this, but as yet it was not understood. The President's explanations, valuable in themselves, might induce further study.

Mr. Ian Robin asked how long one waited in a case of unilateral deafness and tinnitus, before vertigo arose, while making a diagnosis of Ménière's disease. Was it necessary to have tinnitus to diagnose Ménière's? If there were deafness and vertigo without tinnitus could that be put down as Ménière's?

The President, in reply, said that he had intended to present quite a simple little picture of one facet in this very involved and complicated disease. They had described cases of Eustachian obstruction with perceptive deafness, treated them, and all the deafness disappeared. How common was that? So many individuals had said that it occurred that he must accept it, but how often did it occur? He thought it was very rare.

He could not see any reason why there should not be hæmorrhages in the cochlea and thrombosis in a vessel; it would seem inevitable. Twenty years ago he used to write to the doctor and say that that was what he expected had happened, but he thought personally that the general picture showed that the vascular element was not the usual one.

He, the President, thought that Mr. Vlasto had experienced the same condition in a minor degree. Vestibular Injuries

By TERENCE CAWTHORNE, F.R.C.S.

INTRODUCTION

THIS paper is based upon a study of the effects of deliberately destroying the end-organ of the vestibular nerve in the labyrinth for the relief of Ménière's disease in 120 cases and upon the detailed otological examination of a series of 58 closed head injuries whose convalescence was protracted mainly on account of disturbed balance.

In both groups, once the immediate effects of the injury had been overcome and the patients were ambulant, vertigo, easily provoked by sudden head movements, was the predominating symptom; whilst the most constant, and in many the sole physical sign, was an abnormal response to caloric stimulation of the labyrinth. Moreover, it was found that all these cases required the same management to aid in restoring balance and thus encourage their return to normal.

The striking similarity between the two groups, both as regards clinical features and management, led us to consider that the injury was probably in the same place in some cases, though of course it varied both in mode of production and in extent.

It is certain that in the case of labyrinthectomy it is the end-organ of the vestibular apparatus which is damaged, but as yet there is no pathological evidence available to show end-organ damage in cases of vertigo following head injury. Nevertheless the close clinical relationship between the two groups of cases leads one to believe that in both it may be the end-organ in the labyrinth that is the seat of the damage and this belief is further strengthened by the similarity of the physical signs.

The association of vestibular damage with head injuries was noted by S. H. Mygind (1918) who found that 24% of the cases he had examined had genuine vestibular symptoms. Brunner (1928 and 1940) stressed the importance of noting any nystagmus, particularly on altering the position of the head. Barre and Greiner (1932) found vertigo in 54 out of 100 cases of head injury though otological tests did not reveal any correspondence between cochlear and vestibular changes. Linthicum and Rand (1931) urged that post-concussional vertigo should not be dismissed without detailed neuro-otological tests, and Voss (1934) suggested that the term "labyrinthine concussion" might be used for these cases. Glaser (1937) found vestibular abnormalities in 76% of 66 cases, most of which he attributed to central changes. Barmoe and Marks (1941) stressed the value of a full otological examination in all cases of head injury followed by vertigo and mentioned the importance in the caloric test of using both the hot and cold stimulus to bring out any latent tendency to nystagmus.

In the general descriptions of concussion the frequency of vertigo as a sequel of head injury was particularly noted by Osnato and Giliberti (1927) and by Symonds (1937 and 1943) and Russell (1932), all of whom appreciated the possibility of vestibular disturbance in such cases.

MODE OF INJURY

(a) *Labyrinthectomy* (Cawthorne, 1943).—The site and mode of injury in the cases of labyrinthectomy that we have studied are quite clear. After opening into the perilymph space the membranous external canal is seized and removed. This has always resulted in a total loss of vestibular as well as cochlear function. We have found that the same result follows merely opening the endolymph space by tearing the membranous canal across or by coagulating the membranous canal with diathermy.

(b) *Labyrinthotomy*.—Another form of deliberate operative injury to the labyrinth that I think deserves mention is the opening of the perilymph space for the relief of deafness. Here the injury to the end-organ should be slight because an essential precaution of the operation is to avoid damage to the membranous labyrinth. Nevertheless, even when one can be reasonably certain that the membranous labyrinth has not been touched the disturbance produced is instantaneous and considerable and must be due to altered physical conditions rather than to direct injury or inflammatory reaction. This aspect of labyrinthotomy requires careful consideration because it has been my experience that in such cases vertigo forms a prominent and sometimes protracted feature of the post-operative course and prospective candidates for this operation should be warned

beforehand that they may be troubled by vertigo afterwards. They are, of course, helped by the same management as the other cases under consideration.

(c) *Post-concussion*.—Certain experimental work has been done to show that head injuries may be accompanied by changes both in the vestibular end-organ and its connexions in the central nervous system. Brunner (1928, 1940) found that blows on the fixed head caused changes in the peri- and endo-lymphatic spaces and also certain changes, mainly vascular, in the brain-stem as well as in other parts of the central nervous system. More recent work by Denny-Brown and Russell (1941) has revealed that the clinical picture of concussion could be easily produced experimentally by blows from a hammer with a striking speed of up to 40 feet per second upon the occipito-parietal region of animals whose heads were free to move with the impact of the blow. They termed this "Acceleration Concussion". Similar injuries to a fixed head they termed "Compression Concussion". A much smaller striking force was required to produce acceleration concussion than compression concussion and was attributed to a direct physical injury to the neurons which was reversible. It was obtained in the decerebrate animal both with and without section of the 8th nerves.

Nearly all the concussion cases with prolonged vertigo that we have observed were the result of acceleration concussion and I think that there is a very good reason why this is so.

As both the cochlear and vestibular end-organs rely for their essential stimulus upon displacement or deformation by a movement of endolymph, it is reasonable to suppose that if one end-organ suffers actual damage from over-stimulation by excessive endolymph movement, then over-stimulation may in a like manner cause damage to the other end-organ.

In the case of the cochlea, it is known that exposure to loud sounds (e.g. gunfire, boiler-making) may result in a disturbance of the cochlear fluids that is sufficient to cause permanent damage to the organ of Corti.

In the vestibular part of the labyrinth the end-organs (maculæ of the utricle and cupulæ of the canals) are so designed as to be exposed to pressure or traction by displacement of the endolymph in response to acceleration and deceleration movements of the head. As the maculæ and cupulæ are stimulated by the slightest and gentlest movements of the head, it is reasonable to assume that they would be exposed to a heavy strain when stimulated by the sudden and violent jerking of the head that is part of acceleration concussion. It might, therefore, be expected that the vestibular end-organ in the labyrinth would be particularly vulnerable to injury in concussion. The facts that vertigo is the cardinal symptom of a damaged labyrinth and that a frequent sequel of concussion is vertigo support this hypothesis and I hope that it may be possible at a later date to produce more concrete evidence to show that the vestibular end-organ is not infrequently injured in acceleration concussion.

CLINICAL FEATURES

The symptoms and signs that follow immediately upon an injury to the labyrinth are widespread and are often so terrifying in their intensity that observers unused to the ways of the labyrinth may find it difficult to believe that such a profound disturbance can be caused by injury to such a modest organ.

The overwhelming vertigo, the awful sickness and the turbulent eye movements—all enhanced by the slightest movement of the head—combine to form a picture of helpless misery that has few parallels in the whole field of injury and disease.

This lurid picture is, of course, seen when a previously active labyrinth is completely and suddenly overwhelmed and might conveniently be known as the syndrome of acute vestibular failure. The intensity of the symptoms will, however, vary from case to case, depending upon the nature and extent of the injury and they may sometimes be masked by the effects of injuries elsewhere. Fortunately the body is soon able to adjust itself to altered conditions even if normal balance between the two labyrinths is not quickly restored, and within a few days of injury the acute phase dies down, leaving a residue of effects which deserve our very careful attention. This residue is seen after operations on the labyrinth and in the so-called post-concussion syndrome where vertigo in one form or another plays a prominent part. The vertigo, giddiness or dizziness consists of a sensation of apparent movement, either of the subject in relationship to his surroundings or of the surroundings in relationship to the subject. The direction and extent of the apparent movement are immaterial. The essential feature is a sensation of movement that does not, in fact, take place. It is typically provoked by sudden alteration of

A much smaller striking force was required to produce acceleration concussion than compression concussion and was attributed to a direct physical injury to the neurons which was reversible. It was obtained in the decerebrate animal both with and without section of the 8th nerves.

Nearly all the concussion cases with prolonged vertigo that we have observed were the result of acceleration concussion and I think that there is a very good reason why this is so.

As both the cochlear and vestibular end-organs rely for their essential stimulus upon displacement or deformation by a movement of endolymph, it is reasonable to suppose that if one end-organ suffers actual damage from over-stimulation by excessive endolymph movement, then over-stimulation may in a like manner cause damage to the other end-organ.

In the case of the cochlea, it is known that exposure to loud sounds (e.g. gunfire, boiler-making) may result in a disturbance of the cochlear fluids that is sufficient to cause permanent damage to the organ of Corti.

In the vestibular part of the labyrinth the end-organs (*maculae of the utricle and cupulae of the canals*) are so designed as to be exposed to pressure or traction by displacement of the endolymph in response to acceleration and deceleration movements of the head. As the *maculae* and *cupulae* are stimulated by the slightest and gentlest movements of the head, it is reasonable to assume that they would be exposed to a heavy strain when stimulated by the sudden and violent jerking of the head that is part of acceleration concussion. It might, therefore, be expected that the vestibular end-organ in the labyrinth would be particularly vulnerable to injury in concussion. The facts that vertigo is the cardinal symptom of a damaged labyrinth and that a frequent sequel of concussion is vertigo support this hypothesis and I hope that it may be possible at a later date to produce more concrete evidence to show that the vestibular end-organ is not infrequently injured in acceleration concussion.

CLINICAL FEATURES

The symptoms and signs that follow immediately upon an injury to the labyrinth are widespread and are often so terrifying in their intensity that observers unused to the ways of the labyrinth may find it difficult to believe that such a profound disturbance can be caused by injury to such a modest organ.

The overwhelming vertigo, the awful sickness and the turbulent eye movements—all enhanced by the slightest movement of the head—combine to form a picture of helpless misery that has few parallels in the whole field of injury and disease.

This lurid picture is, of course, seen when a previously active labyrinth is completely and suddenly overwhelmed and might conveniently be known as the syndrome of acute vestibular failure. The intensity of the symptoms will, however, vary from case to case, depending upon the nature and extent of the injury and they may sometimes be masked by the effects of injuries elsewhere. Fortunately the body is soon able to adjust itself to altered conditions even if normal balance between the two labyrinths is not quickly restored, and within a few days of injury the acute phase dies down, leaving a residue of effects which deserve our very careful attention. This residue is seen after operations on the labyrinth and in the so-called post-concussion syndrome where vertigo in one form or another plays a prominent part. The vertigo, giddiness or dizziness consists of a sensation of apparent movement, either of the subject in relationship to his surroundings or of the surroundings in relationship to the subject. The direction and extent of the apparent movement are immaterial. The essential feature is a sensation of movement that does not, in fact, take place. It is typically provoked by sudden alteration of

posture or by sudden turning movements of the head. In most cases it is momentary, but in the postural giddiness induced when the head moves forwards or backwards, the sensation may remain for some time, though if the patient can be persuaded to maintain the offending position, the symptom gradually dies down, usually within a minute. In such cases there may be an accompanying nystagmus lasting for about the same time as the vertigo.

In the momentary vertigo following sudden head turning it is not often possible to observe any involuntary eye movements, though sometimes a fleeting flicker may be present. This is the common picture following labyrinth operations and many concussion head injuries. In another group of head injury cases the complaint may be one of continuous slight movement of the ground as though on a slightly rolling ship.

Frequently after labyrinthectomy and sometimes in the post-concussion cases there is a complaint of inability to focus the gaze upon an object for any length of time and of a dislike of looking at quickly moving objects. This is often sufficient to demand an ophthalmic examination which, however, rarely reveals any significant change.

Instability in the dark and on moving up and down stairs or on an inclined plane is usual and, as you will hear later, is catered for in the treatment. A tendency to tire quickly on physical exertion is almost the rule, particularly after labyrinthectomy, and it has been found advisable to warn patients that their return to normal life may have to be gradual and will depend largely upon their ability to overcome this fatigue.

If all these symptoms are not given careful attention and particularly if any adequate explanation is not forthcoming for them, a sense of insecurity may be engendered which will encourage the patient, particularly if he is of an unstable temperament, to drift into a state of chronic invalidism sometimes amounting almost to helplessness.

Headache, which is such a common sequel of concussion, is usually not seen after operation on the labyrinth and cannot, I think, be considered as part of a vestibular disorder, though it may be a most distressing and intractable feature of the post-concussion state. In long-standing cases there is sometimes an excessive and even bizarre disturbance of balance that is clearly out of proportion to the physical signs.

Out of the 58 cases of head injury which were submitted to a full otological examination 56 showed deviations from the normal in their response to caloric stimulation of the labyrinth according to the technique first described before this Section by Hallpike in 1942.

TABLE I

Total cases	58
Abnormal caloric response	56
Directional preponderance	39
Canal paresis	17
Normal caloric response	2

and more fully elaborated by Fitzgerald and Hallpike (1942) and Cawthorne, Fitzgerald and Hallpike (1942) (Table I). Of the remaining two cases, in one the vertigo had disappeared some days before the caloric test and in the other a transient dizziness on bending down had been experienced ever since a head injury two years previously. Of the 56 cases who showed an abnormal vestibular response only 24 had damage to the cochlea (Table II).

TABLE II

Normal hearing	34
Directional preponderance	23
Canal paresis	9
Normal caloric	2
Abnormal hearing	24
Directional preponderance	16
Canal paresis	8

These findings strengthen my belief that in persistent vertigo following concussion the vestibular end-organ is a likely seat of the damage. I would like to emphasize that signs of such damage can only be demonstrated by a careful and detailed otological examination.

TREATMENT

The impression that we have gained from our observation of these cases during the past eight years is that the disturbance of balance caused by an injury to the vestibular apparatus has a profound effect on the well-being of the patient. This is not surprising when we recall that the sense of balance is one of the most primitive faculties with which we are equipped, appearing in the biological scale before the senses of sight and hearing

and possibly before the senses of taste and smell, though of course it has not as yet been elevated to the dignity of a "sense".

To the more impressionable patients a labyrinthine disturbance may make them feel that the end of the world has arrived and I am told by sufferers from sea-sickness that in the acutest phase of their distress, they wish that it had.

Hence it is not surprising that the clinical picture which we have been considering is not infrequently complicated by psychological disturbances which may be sufficient to divert attention away from the underlying cause.

We have found that once the true nature of the disturbance has been established an explanation of the state of affairs, combined with graduated exercises especially designed to encourage head and eye movements, form the most satisfactory basis for hastening recovery (Cawthorne, 1945).

Since the head exercises, which Dr. Cooksey will describe, were instituted by him and carried out by Miss Swan and Miss Hudson at Horton Emergency Hospital, the rate of recovery after operations on the labyrinth has been greatly hastened and we now expect that such cases can resume their normal occupation from within a month of operation, though of course it may sometimes be advisable to recommend a change of occupation. The post-concussion cases, for whom these exercises are particularly useful can, if they are tackled reasonably soon after injury, usually be prevented from drifting into chronic invalidism. The poorest responses to exercises and rehabilitation were always seen in those cases which had been allowed to drift for months with but little planned treatment.

The management of these cases has been made easy and pleasant for me and for my patients because of the way in which it has been possible for Dr. Cooksey and his assistants, the clinicians and ward sisters, all to work together and to share the problems raised by these cases.

I shall always be grateful to Dr. Cooksey and his assistants for their help and to my colleagues at King's College Hospital, the National Hospital, Queen Square, Horton Emergency Hospital and Hurstwood Park Emergency Hospital and to friends elsewhere for referring their cases to us. We have been able to help some, we have failed with others, but I know that we have learnt a lot from all of them.

Rehabilitation in Vestibular Injuries

By F. S. COOKSEY, O.B.E., M.D.

IN 1941 Mr. Cawthorne put to me the principles governing the restoration of fitness after injury to the vestibule and sought my help to develop a system of rehabilitation for these cases. It happened that about the same time I had arranged with the Staff of the Head Injury Centre at Hurstwood Park Hospital to undertake the rehabilitation of late cases of the post-concussion syndrome in my Department at Horton Emergency Hospital. Thus the system of rehabilitation which I am about to describe was developed for the post-concussion syndrome as a whole as well as for the particular problem of vestibular injury.

The symptom complex for which I had to provide consists of headache, vertigo including the so-called "black-outs", impaired mental concentration and deafness in a proportion of cases. Of these symptoms the vertigo may be the most disturbing; but, fortunately is usually amenable to treatment along the lines I shall describe.

Unfortunately the headaches are often persistent and difficult to alleviate. They tend to be severe and have the double disadvantage that they are easily induced by physical or mental effort and are common on first waking. Thus patients are apt to start the day disinclined to engage in any form of rehabilitation. Even if they avoid waking with a headache they find by experience that noise, bright light, talking to a group of people, reading and physical effort bring on a headache. In similar manner the vertigo can be controlled by slow and deliberate movement, but the quick movements of spontaneous activity readily precipitate an attack. Under such circumstances it is natural that, when left to their own initiative, patients seek solitude and inactivity. It might be expected that the symptoms would disappear with the lapse of time; but in many cases this is not so and it is a common experience to see patients with little or no improvement after a year or longer. We believe that failure to recognize the vestibular lesion together with failure to provide adequate measures to restore confidence and to compensate for the damaged vestibular function are the reason for the undue persistence of symptoms.

It has long been recognized in disease and injury of the locomotor system that spontaneous restoration of function does not always follow resolution of the original lesion. Moreover the convalescence of all cases is shortened by systematic measures to assist the recovery more especially when treatment is instituted at the earliest possible moment. We decided to apply the same principles to our patients with concussion injury and also to those cases in which the vestibule had been destroyed in the operative treatment of Ménière's syndrome. We employ graduated physical exercise, mental exercise and occupational therapy. We find that patients can overcome their disabilities by constant encouragement and practice; also, subject to certain limitations in head injuries, the earlier we commence rehabilitation the quicker and better the results.

I attach great importance to four points: First, the initial interview with the patient when we seek to gain confidence and co-operation by explaining the nature of the symptoms and purpose of treatment, with special emphasis on the need to make regular and gradually increasing efforts to do just those things which they find distressing. Secondly, domestic and occupational anxiety must be relieved at the outset by assuring the patients that they will be able to return to their normal work or, if this is unlikely, by explaining the opportunities for vocational training and the operation of the Disabled Persons Employment Act. In this connexion the services of an experienced almoner are essential. Thirdly, a single member of the rehabilitation team should be made responsible for the welfare of these patients and be present whenever they are seen by the surgeon. Fourthly, the programme of physical exercise, mental exercise and occupational therapy should be planned to occupy the whole day and at the same time allow adequate periods for rest between the various activities.

PHYSICAL EXERCISES

The exercises are designed to restore balance as far as possible and to train the eyes and muscle and joint sense to compensate for permanent vestibular dysfunction. Because so many patients are worse in the dark we pay special attention to muscle and joint sense by performing many exercises with the eyes closed. Patients start with individual exercises in bed. In the case of simple concussion exercises may start at seven days. Fractures of the base may start at three weeks and other fractures of the skull as soon as the condition of the patient warrants. In the operative treatment of Ménière's syndrome patients learn the exercises prior to the operation and commence treatment the day after the operation. The time to start exercises must be determined for each patient by the surgeon, but the general rule is the sooner the better.

As soon as patients are able to get up, even if only in a wheel chair, they do their exercises all together in the gymnasium. It is a great advantage to group patients for exercises. In the first place patients encourage each other and those at the beginning of treatment see the progress made by the more advanced cases. Various games can be introduced to vary the monotony of purely remedial exercises. It is economical of staff and all patients receive thorough treatment whereas, in a busy department, individual treatment is time-consuming and apt to be scamped. Moreover the slacker or true malingerer has little chance of escaping exposure by fellow patients with similar disabilities even though he may at first deceive his surgeon.

The table of exercises which is used at each session starts with slow and easy sitting exercises which all patients can manage. First a few loosening movements for the head and shoulders; then head movements with the eyes focusing on near and distant objects; followed by head and arm movements with the eyes closed and directing special attention to training the sense of position in space. Next the movements are speeded up, and slow and quick movements alternated. At this point the beginners drop out and the remainder

progress to similar exercises in standing. Finally only the comparatively fit patients remain for such exercises as walking up and down steps and ladders, first with the eyes open and then with the eyes shut; games with balls and bean bags, when the instructor tosses a ball, high or low, which the patient catches, holds above his head, turns smartly about and bends down to throw the ball back to the instructor between the legs. It is surprising what patients will attempt when spurred on by the instructor and fellow patients. We have seen no untoward effects and it is our experience that, within reasonable limits, the earlier patients are urged to attempt the more difficult exercises the quicker they regain confidence and balance.

In the final stages patients are transferred to the general physical training exercises in which they mix with patients convalescent from various types of disease and injury. In the case of patients who have to return to occupations involving climbing ladders we endeavour to test them out on a small assault course we have built in the hospital grounds. The exercises are under the direction of a physiotherapist who holds a University diploma in physical education.

MENTAL EXERCISES

Many post-concussion patients complain of lack of mental concentration and to assist recovery the education officer takes these patients for an hour each day. By means of play-reading, debates, "brains trusts" and organized study, patients are trained to concentrate on increasingly difficult subjects.

OCCUPATIONAL THERAPY

This combines physical and mental exercise for the purpose of creative work. The object in these patients is to train them to concentrate and to perform the quick and involuntary movements of normal activities. It is useful also to train patients to work under crowded and noisy conditions. Patients start with sitting work involving minimal concentration in the quiet light-handicraft workshop. As they improve they progress to work which involves more concentration and more moving about, including bending and stooping. Finally they progress to the carpentry shop where noise and hard physical work will either restore their confidence to return to industry or reveal the failure of the earlier treatment.

INDUSTRIAL RESETTLEMENT

Rehabilitation in vestibular injuries is not complete until the patients are returned to their normal work or satisfactorily resettled. Patients who are unable to return to their normal work and in whom the disability is likely to last at least six months are qualified to register as disabled persons. Inclusion on the register entitles these patients to vocational training and placing in suitable work. On the recommendation of the surgeon the almoner will arrange with the disablement resettlement officer at the patient's local office of the Ministry of Labour for registration, vocational training and placing in employment.

If it is possible to combine the few cases of vestibular injury with other head injuries and any medical cases of vertigo, grouping them together, it has the advantage of increasing the size of the group. The principle on which we are working is equally applicable to them all.

Mr. Cawthorne now takes his cases of Ménière's syndrome into hospital a week or two before operation, and while he carries out certain investigations, the patients attend exercises in the gymnasium along with the convalescent cases, so that they begin to learn the exercises and are encouraged by seeing the progressive recovery of these other patients. The orthopaedists have also found that to teach patients exercises before operation makes the job much easier afterwards. The time to start the exercises after operation must be determined by the surgeon in each case, but the general rule is the sooner the better.

[At the close of Dr. Cooksey's paper two members of his staff, Miss Swan and Miss Hudson, gave a demonstration of the exercises, one acting as instructor and the other as "patient".]

The President said that in the first place, Mr Cawthorne had pointed out that it was not very infrequent for a pathological lesion to be found in one portion of the labyrinth.

It was a point not sufficiently recognized that while the labyrinth was one organ, and as a rule did suffer disturbance as a whole, both in its auditory and vestibular portions, it was not infrequent, either as a result of disease or of injury, to get a pathological lesion confined to one part.

Mr. Cawthorne was, he thought, a little puzzled as to the explanation of why eye movement should produce a considerable degree of disturbance, as it did in patients with labyrinthine lesions. The eye picture was a very large part of the whole picture. Surely if it was considered that as a result of abnormal sensation from the labyrinth a central disturbance occurred, then all the other sensations as they arrived at the centre were liable to produce abnormal sensory reaction.

After all, the sensations did not arise in the end-organ: the abnormal sensations arose at a higher level. He thought that the answer was that the higher level became disturbed, and all these exercises they had been witnessing were really examples of re-training at the higher level. At least that seemed to him to be the sort of outlook that a simple-minded non-scientific man might take.

He had been interested in Mr. Cawthorne's remarks on acceleration and concussion. In the past one had imagined that concussion was the result of a blow upon this "box" within which there were certain important structures, but he gathered that in quite a proportion of cases of concussion the injury was produced by movement of the head and not by a blow upon the head. That was an important point. He thought it was very probable that his suggestion that a great part of the picture was produced by this movement on the vestibular apparatus was the correct one, but he rather gathered that Mr. Cawthorne was hoping that some experimental work might be done to furnish support for that hypothesis. He had not himself observed that the patients who had a labyrinthine destruction were more easily tired than others, but seeing that their whole locomotor system worked rather abnormally one might expect that there would have to be a rather greater nervous effort made to produce the same output.

He had been taking advantage of the experience gained by Dr. Cooksey's work in the rehabilitation of cases following labyrinthine destruction, and he had been most impressed; he had entirely altered the outlook on the post-operative phase. His own practice was to get these people out of bed on the third or fourth day and one had a picture within two or three weeks that formerly was not obtained for two or three months even if then. He was sure that mass psychology was a very valuable thing to introduce into rehabilitation.

Mr. E. D. Davis said that he could foresee the time when rehabilitation could cure vertigo and the labyrinth operations would be unnecessary. He had had some experience of injuries to the head during the war of 1914-18 and of a number of cases during the recent war. The large majority of fractures of the skull involved the middle fossa and the middle ear. The fracture took the line of the Eustachian tube and the roof of the tympanum and the mastoid antrum and the labyrinth was very rarely injured. It was difficult except in very severe injuries, mostly fatal, to see how the internal ear could be injured because it was encased in the hard petrous bone surrounded by the bony capsule of the cochlea and semicircular canals filled with perilymph and endolymph. He had the notes of 57 cases of injuries of the ear as the result of fracture of the skull and only 5 of these showed any signs of injury to the internal ear. The injury was limited to the cochlea and the labyrinth was normal except in one case. The majority of the patients with fractures of the petrous bones died. Hogarth Pringle (1939) recorded 366 cases of fracture of the skull of which 39 post-mortems showed fractures of the posterior fossa and all the patients who were suspected of having a posterior fossa fracture died. It is the fracture of the posterior fossa which involves the petrous bone. During the war of 1914-18 he was a neuro-surgeon at a casualty clearing station and he only saw about three cases with injuries to the posterior fossa. Most of these cases died on the field of battle.

Gordon Wilson who studied the effect of injuries on the ear (1914-18) stated that it was very rare to find a damaged vestibular apparatus; it was almost always the cochlea.

The injuries to the internal ear could be divided into three groups.

The first group consisted of cases of undoubted and permanent injury to the internal ear showing marked deafness, paralysis of cranial nerves, escape of cerebrospinal fluid, &c. If the hearing did not improve in eight weeks the loss of hearing was permanent. Some of these cases were tested for damage to the vestibular apparatus after recovery from the head injury. The caloric and other tests showed a normal vestibular apparatus in all except one or two.

The second group comprised the so-called cases of psychical deafness. The deafness was usually bilateral and accompanied by other mental and vasomotor disturbances. The hearing tests were often contradictory. When examining such cases it is important to ascertain the position of the patient with regard to the explosion causing the injury. Most injuries to the ear were unilateral and within about 20 feet for the average small bomb. If the patient is immersed in the sea or water the critical distance or danger zone is four times as great, 80 feet. The psychical cases are occasionally suspected of malingering.

The third group are those of temporary deafness, so-called concussion deafness. These patients perhaps sustained other severe injuries and by the time they had recovered from these the deafness had disappeared and the ears were normal. It is difficult to ascertain what anatomical injuries to the internal ear occur. The auditory nerve cannot be seen

like the optic disc but there is a comparison. It is doubtful whether concussion deafness actually exists.

The vertigo following head injuries and fractures of the skull is, in a number of cases, due to damage or contusion of the brain. These patients complained of varying degrees of instability, black-outs, tinnitus, confusion, &c., with normal ears and hearing. The fields of vision may be contracted. The symptoms are not like the rotatory vertigo with unilateral deafness and other signs seen in an aural vertigo. Rehabilitation is valuable for the head injury type of unsteadiness. His experience of the condition of the patient after operations on the labyrinth was similar to that of Mr. Cawthorne. These patients were distressed by intense vertigo and vomiting which took some time to disappear.

REFERENCE

PRINGLE, HOGARTH J. (1939) Some Fractures of the Skull, *Lancet* (ii), 1164.

Mr. F. W. Watkyn-Thomas said that in considering the effects of labyrinthine destruction they had to realize, as Mr. Cawthorne had said, that the labyrinth was part of one of the great protective mechanisms of the body. Its function was to maintain equilibrium; not only a constant relation to fields of gravitational force, but also a constant field of vision. All these things were keyed up on the labyrinth. This meant not only the compensatory movements but everything that went with them, such as the reciprocal innervation and the co-ordinated vasomotor reflexes. A disturbance of the labyrinth meant a complete upset of a mechanism which had been running smoothly for generations, and thus one got the extraordinary general response.

As to the description of labyrinthine vertigo he always recalled the Club of which Mr. Jorrocks was a member in which no member was considered to be drunk so long as he could lie still without holding on to something. It was this which made the recovery so difficult. A disturbance of the labyrinth owing to injury seemed to be a crushing disaster at the time. Curiously, the people whose labyrinths were destroyed for suppuration did not seem to suffer so much after it as those whose labyrinths were destroyed for the cure of Ménière's disease.

On the question of concussion in mastoid operations, he thought that the answer was that they were dealing with an incompressible part of the skull, with a part specially made not to give under a blow but to stand up to a blow. This was suggested by the carefully built-up petrous with its neat balance of hard and elastic bone. He had once or twice noticed some vertigo, after operating on a mastoid with very hard bone, and gougues were not up to the standard required. In one case this lasted long enough to make him fear that he had damaged the external canal, but events proved that all was well.

There was another point about concussion. It was fairly well shown that the crista was anchored at both ends, to the roof as well as to the ampulla. There was one case mentioned by George Jenkins in which a woman was throwing a child up and catching it, and suddenly she went down on to the floor; whenever she put her head into that same position afterwards she got such intense vertigo that Jenkins was compelled to destroy the labyrinth. He had attributed it to dislocation of an otolith membrane.

The question of rehabilitation was most important. Miss Wadge, his chief assistant, pointed out to him some time ago that the sooner one got a patient sitting up after a labyrinth operation the more quickly he recovered. The consequence of that was that they had cut down the time in bed to the very minimum. But it was a new and excellent idea to start these exercises before the operation was done.

Mr. E. D. D. Davis said that in concussion deafness the membrana tectoria was seen to present almost a vertical instead of a horizontal position in the microscope sections. Gordon Wilson had observed this in one case, and he thought it had been found in others.

Mr. H. V. Forster said that in his clear exposition of a difficult subject, Mr. Cawthorne had stressed the degree of suffering experienced by the patient in disorders of the vestibular nervous system.

At a discussion before this Section in 1937 McNally, *Proc. R. Soc. Med.*, 30, 905, had explained that in abnormal labyrinth stimulation the autonomic nervous system was set an almost impossible task of readjustment and how in the resulting confusion nausea was produced.

The labyrinth as an organ of special sense did not rank as high as that "distance receptor" the eye, over whose impressions throughout the ages of man's development the vast area of the cerebral neopallium had grown. But Sherrington nevertheless had described the labyrinth as "the chief proprioceptor of the leading segment of the body which is the head" and had given us a concise understanding of its physiology when he wrote: "The labyrinth keeps the world right side up for the organism by keeping the organism right side up to its external world." Sherrington, C. S., "The Integrative Action of the Nervous System" (1909), p. 336, London.

We could imagine that the congenital deaf-mute in a complete "black-out" would have little to guide him beyond the segmental proprioceptors of the trunk and limbs, but to fall then into deep water these too would fail him with an overwhelming sense of "disorientation". He, Mr. Forster, had been taught many years ago that such an event fulfilling these painful conditions had been recorded.

Mr. I. Simson Hall referred to the method of production of these labyrinthine symptoms. Mr. Cawthorne had stated his belief that they were due to the influence on the nerve

endings. One of the mechanisms was by tension or change in the fluid balance within the labyrinth acting upon the nerve endings. It was a point that deserved attention. Whether one injected alcohol into a labyrinth, ablated the labyrinth by operation, or merely made the smallest possible opening into the labyrinth to let out a little fluid, the symptoms were the same. A labyrinthine crisis of vomiting, giddiness and nystagmus was produced. His experience in making a small disturbance in the fluid of the labyrinth in the fenestration operation tended to show that the influence was through the fluid on the nerve endings.

Mr. C. S. Hallpike said that everybody who had studied this subject would know its difficulties, and he thought it would be generally recognized that Mr. Cawthorne's paper represented a very considerable advance. In particular the methods employed would commend themselves as the right ones to all interested in the scientific side of the subject. It was well known that oto-neurological views in the past had been based very largely upon obscure symptomatology, and not, as they should have been, upon physical signs. Mr. Cawthorne had now made it clear, probably for the first time, that it was possible in many of these cases to elicit meaningful physical signs from the affected vestibular system. From this point he hoped very much that further progress would be rapid.

Sir Milsom Rees said that he had been particularly interested in the 8th nerve, because he was almost sure that it was through this nerve that sense of location and direction was possible, and we were enabled to find our way about, with the aid of some form of magnetism. If this theory was correct for human beings it was likely to be so for birds and all other animals, including eels. Some years ago he read a paper to the Royal Society of Medicine on the role of the labyrinth, but the puzzle to him had been and still was, what part of the auditory apparatus actually gave the sense of location. It was old knowledge that birds and animals had an uncanny way of finding their direction and whereabouts, but how they found it had never been explained. He trusted therefore that some of those interested in the anatomy and physiology of the ear would test his own views on the subject and say whether he was right or wrong.

Mr. Terence Cawthorne said that Dr. Cooksey had stated that some of these cases deceived the surgeon. This was true and in doubtful cases it was often possible to pick out the patients who were "putting it on", by watching the head exercises class at work. It was most instructive to see the way in which the genuine cases behaved and on the other hand the way in which those who were "putting it on" staged their symptoms. Some of these latter would put on terrific turns, rather like a comedian on the music hall stage who pretends to be drunk and seems about to fall into the orchestra.

The President had spoken about the pathological lesion being in one part of the labyrinth. He was inclining more and more to the same view.

He was in agreement with Mr. Davis on the frequency with which fractures of the skull involved the middle ear. He had had the opportunity of seeing several such cases, giving rise to ear discharge and granulations, and in some of these cases the cochlea at any rate had been intact.

Mr. Watkyn-Thomas had mentioned the fact that in cases with suppurative labyrinthitis the vertigo was not so intense as after an operation for Ménière's disease. The reason for this was quite clear. The amount of post-operative disturbance was in proportion to the amount of immediate pre-operative function. In the case of the suppurative labyrinthitis it was possible that the function might have slowly disappeared, whereas in the case of Ménière's disease, particularly if there had been an active labyrinth, it was likely to have been suddenly cut off.

Mr. Forster had mentioned about throwing born-deaf children into baths. There was no reason why such children should not learn to swim because nearly all children born deaf gave an active response to vestibular stimulation.

Mr. Simson Hall had mentioned the altered fluid conditions, and he was sure that they might be expected to play an important part in vestibular disorders.

Dr. F. Cooksey, also in reply, said that he entirely agreed that mass psychology was the key to a large part of this problem. He himself had to be an enthusiast and insist that these patients be spurred on. Danger would only arise if the patients were not carefully selected in the first place by those, like Mr. Cawthorne and the members of the Section, who would guide them as to the essential scientific basis of the disability and principles of treatment.

Some Temporal Bones which had been Subjected to Mastoid Operations.—E. D. D. DAVIS, F.R.C.S.

Mr. E. D. D. Davis exhibited some interesting specimens which he had accumulated over a considerable period of time illustrating some of the naked-eye points in the anatomy and pathology of the middle ear and of operations on the mastoid and labyrinth. The fixing and embedding of the temporal bone in plaster of Paris made macroscopical dissection easier. Mr. Davis said that these specimens were very useful for post-graduate teaching.

Section of Laryngology

President—G. EWART MARTIN, F.R.C.S.ED.

[December 7, 1945]

DISCUSSION ON PENICILLIN IN RHINOLOGY

I. Simson Hall (*Abridged*): Some months ago when supplies of penicillin began to reach the teaching centres in greater quantities a series of experiments was undertaken, designed to explore some of the possibilities of penicillin treatment and to explain some of the good effects which we had already observed in our clinical work. Some types of infection were selected which seemed to be amongst the more urgent problems. These were the common cold, streptococcal infections of the pharynx, Vincent's angina, and sinusitis. The investigation was carried out in Edinburgh Royal Infirmary with Dr. J. F. O. Mitchell as part of the penicillin investigations under Professor J. R. Learmonth. I shall confine myself to cases of acute frontal sinusitis with complications.

These cases all appeared within a few weeks of each other and we were able to form impressions rapidly. Each case had osteomyelitis characterized by a doughy oedema spreading upwards through the hair line, two had subperiosteal abscess, one had meningeal irritation, and one established meningitis and frontal lobe abscess. The organism in three cases was the staphylococcus, in one non-hæmolytic streptococcus, and in one hæmolytic streptococcus. Treatment in each case followed the same lines. The only operative treatment carried out in my department was the insertion, through a one half-inch incision and a trephine hole, of a fine rubber tube into the frontal sinus. The tube was stitched to the skin and the skin closed round the tube. Through the tubes the sinuses were irrigated with saline and a known dose of penicillin was injected at frequent intervals. In one case a double intranasal antrostomy was also carried out. Continuous parenteral administration was also used. The result of this treatment was that all cases were healed and dry and without nasal discharge in less than three weeks: an average of seventeen days.

The case which developed frontal lobe abscess presented the full range of common complications and deserves comment. Our ophthalmological colleagues were of the opinion that the slight papilloedema present at first was due to the high intracranial pressure induced by the meningitis. The excellent progress of the patient seemed to support this opinion, but a return of lethargy and increased papilloedema proved that further treatment was necessary and the patient was transferred to the Neurological Unit under Mr. Norman Dott. Using the customary coronal incision the larger portion of the frontal bone was removed for decompression, and in doing so, the frontal sinuses

endings. One of the mechanisms was by tension or change in the fluid balance within the labyrinth acting upon the nerve endings. It was a point that deserved attention. Whether one injected alcohol into a labyrinth, ablated the labyrinth by operation, or merely made the smallest possible opening into the labyrinth to let out a little fluid, the symptoms were the same. A labyrinthine crisis of vomiting, giddiness and nystagmus was produced. His experience in making a small disturbance in the fluid of the labyrinth in the fenestration operation tended to show that the influence was through the fluid on the nerve endings.

Mr. C. S. Hallpike said that everybody who had studied this subject would know its difficulties, and he thought it would be generally recognized that Mr. Cawthorne's paper represented a very considerable advance. In particular the methods employed would commend themselves as the right ones to all interested in the scientific side of the subject. It was well known that oto-neurological views in the past had been based very largely upon obscure symptomatology, and not, as they should have been, upon physical signs. Mr. Cawthorne had now made it clear, probably for the first time, that it was possible in many of these cases to elicit meaningful physical signs from the affected vestibular system. From this point he hoped very much that further progress would be rapid.

Sir Milsom Rees said that he had been particularly interested in the 8th nerve, because he was almost sure that it was through this nerve that sense of location and direction was possible, and we were enabled to find our way about, with the aid of some form of magnetism. If this theory was correct for human beings it was likely to be so for birds and all other animals, including eels. Some years ago he read a paper to the Royal Society of Medicine on the role of the labyrinth, but the puzzle to him had been and still was, what part of the auditory apparatus actually gave the sense of location. It was old knowledge that birds and animals had an uncanny way of finding their direction and whereabouts, but how they found it had never been explained. He trusted therefore that some of those interested in the anatomy and physiology of the ear would test his own views on the subject and say whether he was right or wrong.

Mr. Terence Cawthorne said that Dr. Cooksey had stated that some of these cases deceived the surgeon. This was true and in doubtful cases it was often possible to pick out the patients who were "putting it on", by watching the head exercises class at work. It was most instructive to see the way in which the genuine cases behaved and on the other hand the way in which those who were "putting it on" staged their symptoms. Some of these latter would put on terrific turns, rather like a comedian on the music hall stage who pretends to be drunk and seems about to fall into the orchestra.

The President had spoken about the pathological lesion being in one part of the labyrinth. He was inclining more and more to the same view.

He was in agreement with Mr. Davis on the frequency with which fractures of the skull involved the middle ear. He had had the opportunity of seeing several such cases, giving rise to ear discharge and granulations, and in some of these cases the cochlea at any rate had been intact.

Mr. Watkyn-Thomas had mentioned the fact that in cases with suppurative labyrinthitis the vertigo was not so intense as after an operation for Ménière's disease. The reason for this was quite clear. The amount of post-operative disturbance was in proportion to the amount of immediate pre-operative function. In the case of the suppurative labyrinth it was possible that the function might have slowly disappeared, whereas in the case of Ménière's disease, particularly if there had been an active labyrinth, it was likely to have been suddenly cut off.

Mr. Forster had mentioned about throwing born-deaf children into baths. There was no reason why such children should not learn to swim because nearly all children born deaf gave an active response to vestibular stimulation.

Mr. Simson Hall had mentioned the altered fluid conditions, and he was sure that they might be expected to play an important part in vestibular disorders.

Dr. F. Cooksey, also in reply, said that he entirely agreed that mass psychology was the key to a large part of this problem. He himself had to be an enthusiast and insist that these patients be spurred on. Danger would only arise if the patients were not carefully selected in the first place by those, like Mr. Cawthorne and the members of the Section, who would guide them as to the essential scientific basis of the disability and principles of treatment.

Some Temporal Bones which had been Subjected to Mastoid Operations.—E. D. D. DAVIS, F.R.C.S.

Mr. E. D. D. Davis exhibited some interesting specimens which he had accumulated over a considerable period of time illustrating some of the naked-eye points in the anatomy and pathology of the middle ear and of operations on the mastoid and labyrinth. The fixing and embedding of the temporal bone in plaster of Paris made macroscopical dissection easier. Mr. Davis said that these specimens were very useful for post-graduate teaching.

clear on the third day and was seen well three months later. In the fifth the organism was *Staphylococcus aureus*. The antrum was clear on the fourth day but the case was not followed up.

A further 8 cases of chronic sinusitis were treated. The results on the whole were disappointing. 3 developed blocked ostia and of these, 2 had intranasal antrostomies performed with satisfactory result. The third refused operation. 3 cases were treated with apparent success, and 2 further cases of chronic sinusitis were treated with penicillin and later required operation.

A further 4 cases of catarrh were also treated with apparent success. The histories varied from two to five years, the chief complaint being of post-nasal mucus. In none of these was there any gross sinus pathology and the clinical findings were congested nasal mucosa in all and excessive post-nasal mucus in 3. All were subjectively improved and in each case I noted an improvement in the appearance of the nasal mucosa. The longest follow-up was three months. These cases were all treated in the spring and summer of this year so that it is premature to pass final judgment on them.

J. F. O. Mitchell (*Abridged*): This report is on the local use of penicillin in the nose and throat.

The clinical work included both experimental and therapeutic applications, and these were controlled by bacteriological studies.

All swabs were at once inoculated on blood-agar plates and incubated for at least twenty-four hours. In addition direct smears were made from swabs of Vincent's infection; and in the case of swabs from patients who had already received penicillin, penicillinase blood-agar plates were used. When there was any doubt as to susceptibility to penicillin, sensitivity tests by the ditch method were performed, using a standard *Staphylococcus aureus* as control.

Penicillin in the mouth and throat.—There, a lozenge was used, and the best was found by experiment to consist of plain 8% agar with about 750 units penicillin. Lozenges could be made to last at least two hours and were administered so as to maintain a constant salivary concentration.

The first stage was one of clinical experiment to determine the efficacy of the lozenge and the best system of administration. It was proved by a series of experiments that administration of four lozenges at two-hourly intervals is enough to produce a sterile faucial field which remains so for about six hours. Practical systems of dosage were administration at 9 p.m., 1 a.m., 5 a.m., 7 a.m., and 9 a.m., for overnight pre-operative preparation, and two-hourly by day and once at night (10 lozenges per twenty-four hours) for maintenance of sterility.

Therapeutic trials were begun with tonsillectomy cases.

The clinical series concerned a total of 76 treated and control cases of tonsillectomy. The treated cases were grouped in three series according to the duration of penicillin treatment which was respectively three days post-operative, twelve hours pre- and three days post-operative, sixteen hours pre- and eight days post-operative. Cases were seen on fourth day, ninth day, and after four to six weeks, and the faucial condition recorded. The results show some striking improvements.

Penicillin therapy greatly improves the local condition and lessens the discomfort especially in the immediate post-operative period, the longer pre- and post-operative therapy giving the best results. In the final result, however, any benefit is much less marked and there it appears that surgical technique plays the major role.

By section of the tonsils removed it was proved that, even after three days pre-operative medication penicillin does not seem to penetrate into and sterilize the depths of the tonsillar crypts and therefore will not cure a chronic tonsillitis.

Vincent's infection also rapidly resolves under penicillin therapy. Treatment was one lozenge two-hourly by day and once at night. No other therapy was considered necessary. The results were almost immediate relief of pain and faecal, complete freedom from symptoms and bacteriological cure within two days, clinical cure and cessation of treatment in an average of four and a half days. There still remains the necessity to clear up any local predisposing factors such as carious or erupting teeth, or dental pocketing.

were removed. The lining of the sinuses was slightly thickened, and was sterile. The abscess was tapped at a subsequent operation and the patient has made an excellent recovery. One more fact may be recorded and that is the result of an observation made at the tapping of the abscess. Prior to this a large injection of penicillin (250,000 units) was given and on the first tapping no penicillin was found, but within a matter of minutes after the tension had been relieved, penicillin was found in the abscess contents, thus confirming the observation that, in presence of high internal pressure, penicillin does not penetrate into intracranial abscess cavities till the pressure has been relieved.

In reviewing this case the question was asked whether, had the presence of abscess been decided earlier, treatment would have differed. The conclusion reached by those handling the patient was that management, whether by good luck or good guidance, was sound.

To summarize: it is suggested that penicillin is no substitute for surgery but that the day of radical surgery as a primary treatment for acute infections of the frontal bone is over; that conservative treatment with penicillin is the treatment of choice until the acute infection is mastered, and that operative measures should follow later if necessary.

R. H. Hunt Williams (Abridged): In order to perfuse the sinuses with penicillin by local as opposed to systemic application one of two methods may be adopted.

First displacement therapy as advocated by Proetz may be used. Secondly repeated puncture may be carried out and the fluid injected. We employ a technique whereby one or at most two punctures of an antrum only are needed and the administration of penicillin left to the nurse.

After preliminary cocaineization the antrum is punctured in the usual way beneath the inferior turbinal with a trocar and cannula. The cannula should be of a slightly wider bore than the standard one so that after removal of the trocar it will easily receive a No. 12 ureteric catheter. A No. 9 catheter, which can be used with a standard cannula, has a slight tendency to become blocked. When the catheter is felt to impinge on the posterior maxillary wall it is withdrawn slightly. The cannula is then removed leaving in situ the catheter which is cut to a suitable length and fixed with strapping to the upper lip and cheek. The catheter ends just in front of the ear. For the frontal sinus I have only attempted this on one occasion. The frontal sinus cannula available was of a too narrow bore but it was found possible to use a fairly wide bore Eustachian catheter to act as a guide to the ureteric catheter which was then successfully inserted into the frontal sinus.

I do not think that perfusion of the ethmoid labyrinth by this method is likely to meet with success as it forms no adequate reservoir for the retention of the fluid.

A preliminary exploration of the sinus with a Watson-Williams syringe is needed in order to obtain a bacteriological report. Where penicillin is used the presence of resistant organisms such as *B. coli*, *pyocyanus* or *proteus* is a contra-indication.

Dosage.—The dosage had to be empirical. For local application of penicillin to other regions such as the eye, skin or deep wounds a strength of 250 to 500 units per c.c. is adequate. In order to get comparative results we employed a standard dosage in the earlier cases. 1 c.c. doses were given hourly by day and three-hourly at night for forty-eight hours and then three-hourly for a further forty-eight hours, 250 units per c.c. Total dosage was 14,000 units. In addition after the first forty-eight hours, the sinuses were irrigated before the morning and evening dose with 50 c.c. of warm saline and the nature of the washout recorded. This irrigation is not an essential part of the procedure but gives some indication whether improvement is taking place and whether further treatment is likely to benefit.

Later investigations showed that an aqueous solution of 12% sodium iodide which has roughly the same consistency as a penicillin solution and is radio-opaque will remain in an antrum from sixteen to thirty-six hours. The later cases were therefore given 5 c.c. doses at eight-hourly intervals, the total dosage in four days being 15,000 units.

Five cases of acute or subacute sinusitis were treated; 4 were cases of maxillary sinusitis, 1 was a case of pansinusitis; of these 5, 3 were members of air crew. 2 were back flying within three weeks and 1 in a month.

The first, a case of severe sinusitis, was symptom-free in three weeks. The second was clear in four days and was seen well a month later. The third, a case of pansinusitis, was discharged on the eleventh day, and was flying one month later. The fourth was

clear on the third day and was seen well three months later. In the fifth the organism was *Staphylococcus aureus*. The antrum was clear on the fourth day but the case was not followed up.

A further 8 cases of chronic sinusitis were treated. The results on the whole were disappointing. 3 developed blocked ostia and of these, 2 had intranasal antrostomies performed with satisfactory result. The third refused operation. 3 cases were treated with apparent success, and 2 further cases of chronic sinusitis were treated with penicillin and later required operation.

was tried, and in a third, although the interval was kept at four-hourly, the course was started twenty-four hours before operation. The usual starting time with the other two series was immediately the patient came round from the anæsthetic. Whichever method was used, we tried to make the penicillin administration as continuous as possible, allowing the patient respite only between the hours of 10 p.m. and 6 a.m., when he was sleeping.

Clinical results.—We realize that the series is too small to draw any dogmatic conclusions. Two of the symptoms recorded, namely pain and difficulty in swallowing, are subjective in character, and even the state of the tonsillar bed may give rise to differences of opinion. In addition, both the clinical and bacteriological results may be modified by concomitant sinus infection, previous attacks of quinsy, the degree of chronic tonsillitis, the presence or absence of adhesions, the interval between operation and the last attack of acute tonsillitis, and also the skill of the operator.

There were no outstanding differences in these respects between the penicillin-treated group and the control group. Consequently we feel that the two series are comparable.

All the tonsils were removed by dissection and the guillotine was not used.

The outstanding difference between the two series was the state of the tonsillar bed. The exudate that formed in the tonsillar bed of those patients who were treated with the penicillin pastilles was not nearly so marked. As a result the slough was not so deep and the wound healed with far less scarring of the faucial pillars. Fewer patients in this series complained of the late pain which shoots up to the ears when the slough is separating, and they appeared to swallow with greater freedom. With regard to the temperature, although there was no real disparity between the numbers of penicillin-treated patients and the control group who showed some rise in temperature, yet the rise was seldom so high in the penicillin-treated group, nor did it occur so frequently. This advantage was more obvious when we adopted the method of starting penicillin treatment pre-operatively, and in this series (10 cases) no rise of temperature was recorded, even on the evening of operation.

Bacteriological results.—Whichever method of administration was used, there was no appreciable difference in the bacteriological results. The sensitivity of all the organisms was tested against the Standard Oxford staphylococcus. Though it was not possible to indicate all the shades of variation in sensitivity that were found, the following divisions were made: (a) Sensitivity equal to that of the Standard Oxford staphylococcus; (b) sensitivity less than that of the Standard Oxford staphylococcus; (c) penicillin-resistant.

By the fifth day of treatment with penicillin it was found that there were definite changes between the two series as far as the bacteriological results were concerned. Whereas the plates from the control series still showed a mixed growth of the usual type, those from the penicillin-treated series were slimy in appearance with an easier differentiation of the colonies. Some of these were composed of non-sensitive "coliform" and diphtheroid organisms only: a few showed a scanty growth of sensitive staphylococci or streptococci, but in many there was quite a profuse growth of staphylococci which were of a penicillin-resistant type. Generally these colonies were mixed with some of the Gram-negative organisms and the cultural appearance suggested that they belonged more to the "*albus*" type than to the "*aureus*." As far as the other organisms were concerned the *Micrococcus catarrhalis* was generally sensitive, whilst the diphtheroids seemed divided in their sensitivity, some being entirely resistant. In two patients some penicillin-resistant pneumococci were cultured after penicillin treatment, though these organisms had not been found in the pre-operative swabs.

A further point of interest is the post-operative increase in the "coliform" organisms among the penicillin-treated group. It is now recognized that penicillin seems to favour the growth of these organisms and a similar result was obtained when the local application of penicillin was tried for the treatment of chronic suppurative otitis media.

In four patients who were given a pre-operative course of penicillin, the bacteriological flora was reduced to a few Gram-negative bacilli. After the tonsils had been dissected out, cultures were taken from the centre of the tonsils and in each case we obtained a profuse growth of *Streptococcus hæmolyticus* and *Staphylococcus aureus*. Both of these organisms were of standard sensitivity. This suggests that the local application of penicillin by means of pastilles will not cure a chronic tonsillitis. This is not surprising as, though penicillin is a very diffusible substance, it cannot be expected to penetrate to the bottom of the tonsillar crypts.

Acute streptococcal tonsillitis, another common condition, usually responds to the systemic use of sulphonamides. Penicillin lozenges now hold prospect of effective local antibacterial action coupled with the advantage of elimination of the patient's infective droplet spray. In early or catarrhal tonsillitis where the infecting organisms are as yet superficial, local penicillin therapy alone produces clinical and bacteriological cure within two days. When infection has reached the tonsillar crypts, however (follicular tonsillitis), it is in part beyond the reach of locally applied penicillin and with constitutional disturbance systemic sulphonamide, bismuth or penicillin is indicated, but cure is accelerated by the use of local penicillin also, which will attack the infection from the surface and at the same time sterilize the droplet spray. In my series, two identical cases were cured, one in three and a half days using systemic sulphonamide and gargles, the other in forty-eight hours using systemic sulphonamides and also penicillin lozenges.

The use of penicillin lozenges alone in a severe follicular tonsillitis will not prevent its progressing to *peritonsillar abscess*, since local penicillin does not penetrate the crypts, and once pus has formed, the condition demands surgical intervention.

Streptococcal carriers present a difficult problem to which no effective answer has yet been found. Although cases can sometimes be cleared by local gargles and paints and sulphonamides, relapse is common. Local penicillin clears them only as long as they continue to use the lozenges. Perhaps the combination of sulphonamides and prolonged local penicillin will provide the answer.

Penicillin in the nose.—There it was applied as a powder diluted with glucose to which was added $\frac{1}{2}\%$ menthol. Each patient received 86 mg. pure penicillin diluted to 2 grammes. Here also clinical experiments were deemed necessary, and these, although inadequate for final conclusions, showed that both the normal commensals and susceptible pathogens are rapidly eliminated by the use of penicillin snuff.

Therapeutic trials concerned its use in the treatment of the common cold and comparison with a control snuff of menthol $\frac{1}{2}\%$ in glucose, and with a proprietary suspension of "mickraform" sulphathiazole in paredrine. Penicillin and control snuffs were administered from a special glass applicator from which the patient inhaled a dose of snuff every two hours.

Cases, 38 in number, were divided into two groups, early and late. From these results it would appear that local penicillin snuff administered two-hourly for four days will effectively prevent the secondary invasion of pyogenic organisms (in every case in the trials), and if they have already gained a foothold, will completely eliminate the purulent discharge and produce cure in the majority of cases (6 of 9 trials) and considerably reduce it in the others.

Adjuvants to penicillin snuff were used in some cases. When nasal obstruction was marked and prevented the initial use of the snuff, 2% ephedrine-saline nose-drops, or menthol inhalations were used until adequate airway was obtained. In another case usually progressing to sinus catarrh and toxæmia, the latter but not the local symptoms responding to treatment in bed with sulphadiazine, the combination of local penicillin and systemic sulphadiazine produced complete cure within thirty-six hours.

E. G. Collins, P. D. Eeman, and A. R. T. Lundie: *Local penicillin therapy in tonsillectomy (Abridged)*: In February 1945 we started an investigation at a military hospital in Great Britain with a view to assessing the value of this form of therapy, and we attempted to determine the best method and routine of administration. There were 31 patients in the series which had penicillin treatment and 29 patients in the control series. They were not given sulphonamides in any form.

Bacteriological examination.—All the patients' throats were swabbed and bacteriologically examined pre-operatively, and in the first 20 cases post-operative swabs were taken on the third, fifth, seventh and ninth days, but later we reduced the post-operative bacteriological examinations to two: swabs being taken on the third and fifth days only.

Penicillin pastilles.—The first 10 cases were treated with home-made pastilles. Pastilles (lozenges) of 500 unit strength with an agar base were used for the remainder of the investigation; they lasted on an average about two hours.

Method of administration.—The pastilles were placed in the buccal sulcus, and the patient was instructed not to suck or chew them. The course lasted five days, but certain variations were made in the intervals of administration. In one series we gave the pastilles at two-hourly intervals, in a second series the effect of a four-hourly interval

R. J. V. Pulvertaft said that nothing had been mentioned about the inhalation of penicillin mists, but the subject had been much discussed in America and had been followed up in this country by Dr. Mutch of Guy's. He had tried it himself using the Collison inhaler. In the first place, the distribution of the drug was odd and unexpected with anything inhaled. It was chiefly collected on the turbinates and in the posterior pharynx, and after that in the œsophagus and stomach. It did not go down, in the earlier stages, through the trachea into the lung. It was concentrated in a very effective way in the turbinates and nasopharynx, but not on the tonsils. When inspired in this way, if a swab of the tonsils were taken it would be found that for a long time no inhibition was obtained at all on test plates. The drug was absorbed in the blood in highly bacteriostatic concentrations. It was too early to say that any result had been obtained in the treatment of nasal infections, and the treatment had the disadvantage that the patient went round smelling strongly of "cat". Much depended on the size of the particles introduced. If a relatively large particle mist were introduced by the Milton Dynalysor it tasted abominably, but given with a Collison inhaler in particles of 3 to 5 μ , it was quite sweet. Several patients said that their noses flowed more vigorously after inhalation. A great deal had been claimed for it in America, and it would be interesting to learn whether anybody had followed it up.

A. S. H. Walford said that it seemed to him necessary to find some method of dealing with the subacute and chronic case before any real good could be said to be done. He had found repeated instillation of the antra by inserting a trocar and cannula, as designed by Mr. Asherson, then withdrawing the trocar; leaving the cannula in situ for four or five days, to be effective. The antra could be sucked dry, and 2 or 3 c.c. of penicillin solution put in every six hours. He felt that theoretically that was more likely to work than most other methods, and in fact it did seem to work better. When they said that penicillin would not replace surgery he could not help thinking that that was defensive on their part, at least to some extent. It would not replace deep surgery, but he believed that if they knew how to use it, a great deal of surgery in acute cases would be abolished.

T. B. Jobson described the case of a lady aged 45, who in 1933 had a discharging antrum, which was opened and curetted first through the nose and a year later by Caldwell-Luc. The antrum still continued to discharge, and gradually it adopted a habit of discharging green crusts, which were washed out every few days. After ten years she came under his care, still discharging the green crusts, feeling ill, and having chronic headaches. Penicillin was given systemically every three hours and locally injected into the antral cavity. The antrum was washed out with saline first, and then the penicillin was injected. After ten days of that treatment the antrum was apparently perfectly clear. The washouts showed no pus or mucus, there was no green slough, and she had continued up to date with neither discharge nor headache.

In another case, a child of 7, on whom double antrostomy was done, all sorts of washings were carried out, but no form of irrigation seemed to make any difference. The child was then given only topical treatment with penicillin. She showed no improvement whatever for two weeks, still having a great deal of dirty slough, and then suddenly she changed, and the wash-out became perfectly clear. She had continued well.

[15.3.46. Dr. Jobson reports that both these cases relapsed a month later.]

H. V. Forster said he would like to hear opinions as to whether penicillin should be used prophylactically before performing even conservative intranasal operations in cases of advanced pansinusitis? Post-operative complications were rare after these procedures in E.N.T. work but he had seen two or three cases of osteomyelitis of the upper maxilla with involvement of the ascending nasal process and the hard palate as sequelæ. Were they to do an extensive and mutilating operation in an attempt to save life, or would penicillin now come to the rescue? Would Mr. Hall or any other member who had treated such a desperate case kindly offer their advice?

A. W. McCay mentioned the case of a patient who had a chronic infection of her left antrum on which an intranasal antrostomy was performed. Ten days later she was readmitted to the hospital with a spreading osteomyelitis of the left maxilla. An extensive Caldwell-Luc operation was performed and the patient put on penicillin, in all one million units were given and this was combined with large doses of sulphathiazole. He was glad to say she made a complete recovery. He also mentioned a case of cavernous sinus thrombosis in a boy of 16 who made a complete recovery with the same treatment.

CONCLUSION

We consider that the treatment of tonsillectomy patients by penicillin pastilles is of value. The results are not dramatic but there is a reduction in the amount of exudate formed in the tonsillar beds and of the surface slough. This results in less scarring and, on the whole, the immediate post-operative symptoms are less marked. We consider that the best method is to start the penicillin treatment twenty-four hours before operation and to continue it for five days at three-hourly intervals, recommencing treatment as soon as the patient recovers from the anaesthetic. We found that if the penicillin pastilles are made with an agar base, a two-hourly interval is too short to allow the pastille to dissolve completely, whilst if the interval is increased to four-hourly, we think a sufficient concentration of penicillin is not maintained.

R. G. Macbeth: The investigations now proceeding were made in order to see how penicillin might be used in the ordinary cases of infection in laryngology and in rhinology. To do this three methods have been employed in cases of the ordinary type. First we tried the suction displacement method using 250 or 500 units of penicillin per c.c. as the lotion. Secondly we tried an emulsion made up with lanette wax containing 400 units per gramme, which was injected into the antrum in the acute or subacute or chronic cases and left in for a week. Thirdly we tried the effect of systemic penicillin in a few chronic cases.

Suction displacement was peculiarly successful in clearing up residual ethmoiditis after acute infections. In acute cases of infection of the frontal sinus or antrum the method has proved disappointing. All these cases have been bacteriologically controlled. The acute cases have done very much better than the chronic cases. The emulsion was injected through a wide cannula in amounts varying from 5 to 8 c.c., depending upon the size of the patient. At the end of the week the wash-out was done again, and any of the emulsion remaining which had been yellow when it went in was now colourless. The culture might still be positive, but the pus was much less in amount and might even have disappeared. In the chronic cases, on the other hand, this line of treatment has proved disappointing and almost all the cases have come to operation sooner or later.

The systemic application of penicillin has not been given deliberately to an uncomplicated acute case, but it has been observed that where the more serious complications were present, such as meningitis, provided the sinuses were in fact draining, the sinusitis cleared up well. This has been confirmed both by bacteriological control and by X-rays. Chronic cases have proved uniformly disappointing.

One type of case in which great temporary benefit has been obtained is atrophic rhinitis. The bacteriological picture was usually a mixed one, with staphylococci, diphtheroids and coliform organisms, but with the use of soaks or suction displacement the Gram-positive organisms disappeared. They are liable to recur, however, with undiminished vigour on cessation of treatment.

Penicillin is very valuable when given prophylactically after major operations upon the larynx and pharynx. Its use has reduced post-operative sepsis in such cases almost to vanishing point.

The President congratulated the openers of the discussion on bringing forward their results with judgment and not too much enthusiasm concerning a drug which had, unfortunately, been boosted so much in the Press; whereas penicillin, as Mr. Simson Hall had stated, was no substitute for surgery but an ideal adjunct.

His early experience of penicillin was not a very happy one. Within a period of six weeks he had seen and treated four cases of osteomyelitis of the frontal, referred to him after operation in other hospitals. They were all treated with penicillin. In each case the frontal sinus was opened radically but not obliterated. In the first case the osteomyelitis apparently cleared satisfactorily but, unfortunately, the patient was not X-rayed before leaving hospital. Six weeks later she reported back and while waiting to be seen developed an acute headache and died within one hour. The second case had an identical history, cleared up in the same way and exactly six weeks later complained of headache and died within an hour. In both cases an abscess had developed and burst into the frontal lobe. With the experience of these first two cases the third case was X-rayed at intervals. An abscess developed silently and was opened through the posterior wall of the frontal, the patient making a perfect recovery. The fourth case cleared up satisfactorily.

R. J. V. Pulvertaft said that nothing had been mentioned about the inhalation of penicillin mists, but the subject had been much discussed in America and had been followed up in this country by Dr. Mutch of Guy's. He had tried it himself using the Collison inhaler. In the first place, the distribution of the drug was odd and unexpected with anything inhaled. It was chiefly collected on the turbinates and in the posterior pharynx, and after that in the œsophagus and stomach. It did not go down, in the earlier stages, through the trachea into the lung. It was concentrated in a very effective way in the turbinates and nasopharynx, but not on the tonsils. When inspired in this way, if a swab of the tonsils were taken it would be found that for a long time no inhibition was obtained at all on test plates. The drug was absorbed in the blood in highly bacteriostatic concentrations. It was too early to say that any result had been obtained in the treatment of nasal infections, and the treatment had the disadvantage that the patient went round smelling strongly of "cat". Much depended on the size of the particles introduced. If a relatively large particle mist were introduced by the Milton Dynalysor it tasted abominably, but given with a Collison inhaler in particles of 3 to 5 μ , it was quite sweet. Several patients said that their noses flowed more vigorously after inhalation. A great deal had been claimed for it in America, and it would be interesting to learn whether anybody had followed it up.

A. S. H. Walford said that it seemed to him necessary to find some method of dealing with the subacute and chronic case before any real good could be said to be done. He had found repeated instillation of the antra by inserting a trocar and cannula, as designed by Mr. Asherson, then withdrawing the trocar, leaving the cannula in situ for four or five days, to be effective. The antra could be sucked dry, and 2 or 3 c.c. of penicillin solution put in every six hours. He felt that theoretically that was more likely to work than most other methods, and in fact it did seem to work better. When they said that penicillin would not replace surgery he could not help thinking that that was defensive on their part, at least to some extent. It would not replace deep surgery, but he believed that if they knew how to use it, a great deal of surgery in acute cases would be abolished.

T. B. Jobson described the case of a lady aged 45, who in 1933 had a discharging antrum, which was opened and curetted first through the nose and a year later by Caldwell-Luc. The antrum still continued to discharge, and gradually it adopted a habit of discharging green crusts, which were washed out every few days. After ten years she came under his care, still discharging the green crusts, feeling ill, and having chronic headaches. Penicillin was given systemically every three hours and locally injected into the antral cavity. The antrum was washed out with saline first, and then the penicillin was injected. After ten days of that treatment the antrum was apparently perfectly clear. The washouts showed no pus or mucus, there was no green slough, and she had continued up to date with neither discharge nor headache.

In another case, a child of 7, on whom double antrotomy was done, all sorts of washings were carried out, but no form of irrigation seemed to make any difference. The child was then given only topical treatment with penicillin. She showed no improvement whatever for two weeks, still having a great deal of dirty slough, and then suddenly she changed, and the wash-out became perfectly clear. She had continued well.

[15.3.46. Dr. Jobson reports that both these cases relapsed a month later.]

H. V. Forster said he would like to hear opinions as to whether penicillin should be used prophylactically before performing even conservative intranasal operations in cases of advanced pansinusitis? Post-operative complications were rare after these procedures in E.N.T. work but he had seen two or three cases of osteomyelitis of the upper maxilla with involvement of the ascending nasal process and the hard palate as sequelæ. Were they to do an extensive and mutilating operation in an attempt to save life, or would penicillin now come to the rescue? Would Mr. Hall or any other member who had treated such a desperate case kindly offer their advice?

A. W. McCay mentioned the case of a patient who had a chronic infection of her left antrum on which an intranasal antrotomy was performed. Ten days later she was readmitted to the hospital with a spreading osteomyelitis of the left maxilla. An extensive Caldwell-Luc operation was performed and the patient put on penicillin, in all one million units were given and this was combined with large doses of sulphathiazole. He was glad to say she made a complete recovery. He also mentioned a case of cavernous sinus thrombosis in a boy of 16 who made a complete recovery with the same treatment.

Mr. J. F. Simpson said that he had recently had a case of maxillary sinusitis which even after a bilateral Caldwell-Luc operation still had a foul discharge. Culture showed a proteus and pyocyanous infection. Under the combined treatment of penicillin and a 2% solution of phenoxetol applied locally the case had done very well, the previous yellow foul discharge completely disappearing.

I. Simson Hall, in reply, said that on the question of prophylactic penicillin, except with regard to such simple administrations as lozenges or snuff, he thought there was no case made out for any such drastic treatment. It was not wise or useful to push needles into people just in the hope of curing the exceptional case which might occur two or three times only in one's professional life.

R. H. Hunt Williams said that the frontal sinusitis case he had shown, in which a ureteric catheter had been used, had a pyocyanous infection which was apparently cleared up with phenoxetol.

J. F. O. Mitchell, also in reply, said that on the question of penicillin mists, when they were considering starting the series of cases he had mentioned in his paper, they debated whether solution or snuff would be better. They decided that when a snuff was inhaled it followed the course of the inspired air, adhering to the mucous membrane and giving a higher and more lasting concentration, and in view of this and of the fact that it was much handier for the treatment of the ambulant patient, they decided that the use of snuff would be better than solution or very fine mist. Penicillin lozenges alone were of very little use in cases of follicular tonsillitis because the penicillin did not penetrate into the depth of the crypt. In such cases he used sulphonamides systemically and penicillin locally.

E. G. Collins said that he could not presume to answer a question which had been asked as to the potency of certain penicillin preparations. But in the case of the Burroughs Wellcome lozenges the potency of penicillin in the lozenge had been tested. It was a bacteriological test and there proved to be very little deterioration with keeping.

[January 8, 1946]

Personnel Selection: By Whom?

By ALEC RODGER

THE working population of this country consists of approximately twenty million persons. Nineteen millions of them are employees of somebody else and so have to go through some sort of personnel selection procedure at least once in their lives. Many have to go through the process many times; for example, when they are seeking to change their employer, or when they are applying for promotion or transfer under the same employer.

The amount of personnel selection work to be done is therefore enormous. And relatively little of it is being tackled by really sound methods. In the circumstances, it is not surprising that people with Service personnel selection experience, acquired mainly during the recent war, have been thinking a great deal about the application of that experience to civil life. But it is surprising, I suggest, and even a little alarming, that some among them seem prepared to model their plans very closely indeed on those adopted by the Services, and to advocate schemes which would involve a vast amount of centralized, or at least regionalized, personnel selection.

I want to propose a substitute for these schemes. Let me start off with three facts:

First, vital though personnel selection often seems to those of us who are engaged upon it, it is not widely regarded as a particularly important activity. In an ordinary industrial or commercial undertaking, personnel selection is only one function of several carried out by the personnel department; and the personnel department itself is not always "on the top line". The Chief Inspector of Factories, in his Report for 1943, gave the results of an analysis of the position occupied by the heads of personnel departments in factories. In 30% the senior officer was found to be responsible to the managing director; in 21% to another director; in 46% to the works manager; and in 3% to the works engineer or the secretary of the company. Thus, in about half the factories the head of the personnel department had no uninterrupted approach to the board room.

Secondly, the great majority of employing organizations in this country are very small. About 90% of them employ fewer than 250 people. For most of them, therefore, personnel selection is an occasional affair. But it is one which they tend to regard as very much their own concern. Maybe times will change, but it is worth remarking that at present my point holds good of quite large organizations, because most of them allow a high degree of autonomy to their constituent companies and do not usually centralize their personnel selection work, except when they are handling the appointment of senior executives.

Thirdly, for certain large groups of workers, mainly of the machine-operator kind, comprising about a quarter of the gainfully employed, personnel selection is becoming decreasingly important. Considerable attention is being devoted nowadays, by industrial psychologists and others, to what is sometimes called "work-simplification", through improvements in the design and lay-out of equipment, in methods of work, and in methods of training for work. All this is tending to make more and more employments fall within the competence of a larger and larger proportion of the working population.

I have mentioned these three facts, because they must be taken into account, if our discussion of civilian personnel selection problems is to be realistic. We must recognize that, although the field is enormous, it is not generally held to be of first-rate importance; it is split up into little pieces which cannot easily be made into one large piece, or even into several fairly large pieces; and parts of it are decreasing in significance.

But, it may be asked, isn't this a strangely pessimistic argument? Why shouldn't the Ministry of Labour and National Service use its now powerful position to urge the importance of personnel selection, and why shouldn't it decide to offer a personnel selection service to employers? I hope the Ministry will urge, constantly, the importance of personnel selection; but, both as an industrial psychologist and as a private citizen, I hope it will resist the coaxing of those who want it to undertake personnel selection duties on behalf of employers. As an industrial psychologist, I doubt whether the Ministry could be expected to compete with the task, unless it possessed a large army of specially trained technicians. As a private citizen, I think that any such arrangement would rightly be regarded as undesirable. Certainly, the job of making it compatible with the doctrine of "freedom of choice of employment" would be a tricky one.

It may be suggested, however, that the rejection of a centralized or regionalized industrial personnel selection scheme would throw on to employers too much responsibility for seeing that misfits were avoided. I doubt whether it would. It seems to me that the real solution of this problem lies in the development, by the Ministry of Labour and National Service, aided by the Ministry of Education, of a first-rate vocational guidance system. Personnel selection is in practice an employer's approach to the "round-peg" problem. In vocational guidance we have the approach of the private person, who comes along not as a candidate for a particular vacancy but as an individual seeking advice. If the Ministry of Labour were able to strengthen still further its present vocational guidance schemes for young people and adults, and to ensure that employers were only rarely faced with really unsuitable candidates, whose unsuitability they found it hard to detect, industry's personnel selection problem would be much nearer solution. Broadly, then, I would say: Let us press for the development of official vocational guidance rather than for the development of official personnel selection. (There must, of course, be official personnel selection for Government jobs.)

To all this, however, I must add three comments: First, the successful working of any such plan would involve the Ministry of Labour in the arrangement of thorough training courses for carefully selected advisory officers, and in the arrangement of a scheme whereby these advisory officers were able to keep in frequent and regular touch with each other and with the people who had trained them. I realize that this is more easily proposed than put into practice, partly because it raises difficult questions—difficult from the point of view of the Treasury—about the extent to which civil servants in certain classes should be permitted to become specialists; but I cannot see any other way of tackling the problem. Personally, as I indicated to the Hankey Committee on Higher Appointments two years ago, I would like the Ministry to set up centrally a model Appointments Office, Local Office and Juvenile Employment Office, which would serve as a composite training unit for its interviewing staff. This unit, which would train people "on the job", might have the assistance of both psychiatrists and industrial psychologists, and of any others—for example, economists—whose help might be useful.

Provided there were available a really good system of post-training supervision, the training course itself need not last more than three months. I am not hopeful of anything satisfactory being done under that time. Before the war, new members of the vocational guidance staff of the National Institute of Industrial Psychology were not generally permitted to send out reports on their own responsibility until they had spent about a year there. I must admit, however, that we were dealing almost exclusively with the vocational guidance problems of young people of what might be called Appointments Office level; that is, they were mostly the moderately able sons and daughters of the relatively well-to-do. I must admit, too, that we were trying to produce written reports which would, to a sufficient extent, stand up to the criticism not only of our victims but also, sometimes, of their parents, headmasters, family solicitors and family doctors, and occasionally of psychiatrists and Ministry of Labour officials. All this made us rather careful, and it is probable that with more thorough organization and less concern for the views of our many potential critics we could have cut down that basic training period.

But of one thing I am quite certain, and that is that the art of vocational guidance cannot be taught in short courses which consist of lectures with no—or hardly any—practical work. Possibly such courses have some use as a sort of "first aid" arrangement, but that is scarcely what is needed. I emphasize this point, because on a number of occasions during the past few years I have had to meet, in some way, requests for lectures and discussions from people who are quite certain that industrial psychologists (and psychiatrists, too) can give all the instruction they need to give through one or two lectures.

And now for my second comment on the development of the Ministry's vocational guidance service. It is evident from pre-war vocational guidance experience, and from wartime personnel selection experience, that a considerable measure of sound self-guidance and self-selection can be stimulated by the provision of relevant information about occupations. When the Royal Navy's present personnel selection scheme was instituted, in the summer of 1941, a cue was taken from the vocational guidance work of the NIIP, and stress was laid on the desirability of providing candidates with an "information service" about naval employments. At the Combined Recruiting Centre stage, a simple descriptive leaflet was made available to them before they had their interview with the Naval Recruiter. (In fact, through the co-operation of the Ministry of Labour it was sent out some days in advance to all men and youths, called up under the Armed Forces Act, who had at the time of their registration expressed a preference for the Navy.) In the Entry Establishments, where the further allocation of recruits was carried out, information about the jobs available was purveyed by means of informal

lectures, by posters and photographs, and occasionally by films and displays of equipment. In these ways new entries to the Service were given some appreciation of the duties involved in the various branches, and of the qualifications required for entry to them and progress in them. The self-selection thereby introduced contributed quite substantially, I am sure, to the success of the whole personnel selection scheme.

My third comment must be on the importance of a point of economics. We have all been made aware of the necessity for an enormous increase in our export trade. But the working population is shrinking, not only because of the fallen birth-rate are coming upon us but also because the 1944 Education Act will—over a period of a few years—result in the delayed entry of hundreds of thousands of young people to the labour market. It will no doubt be difficult for us to escape “direction” of some sort. Presumably we shall seek to have our peacetime direction done for the most part by economic rather than legal sanctions; that is, by the manipulation of wages rather than by telling people exactly where they must go and what they must do. I suggest that a planned wage structure for the whole of industry, aided by a sound vocational guidance scheme, for adults as well as juveniles, and supported by a really good, well-balanced “information service” about the employments available, might gain for us most of the advantages of a less palatable system.

But, obviously, even with the best vocational guidance scheme imaginable, there will still be a need for personnel selection by employers. How should this be done? So far as the bulk of the personnel selection work is concerned, the answer is, I suggest, fairly clear. It should be carried out by suitable members of a firm's personnel department who have received appropriate training in interviewing, in record-keeping (a very important matter) and in the use of any selection tests which may be judged suitable. The experience of the NIIP suggests that this training can most economically be given in short courses of lecture-discussions and demonstrations, organized for groups of people at some central place, followed by individual practical work on the home-ground of each of the firms represented. This arrangement for the practical work is very desirable, in order that at least one of the lecturers might have an opportunity of acquainting himself with the particular nature of the firm's selection problems. It is desirable, too, that this same lecturer should be able to continue his tuition through occasional visits, and that he should be in a position to provide his students with good notes. (And among these I personally would include, until something more appropriate becomes available, a copy of a booklet which is now part of the equipment of Personnel Selection Officers in the Royal Navy. It is called *An Employee Evaluation Manual for Interviewers*, and it is published by the Psychological Corporation of New York.)

Let us take up separately the problem of selecting personnel for senior appointments or for some form of advanced training. To what extent can we expect industry to adopt methods similar to those thrashed out during the past four years by the War Office Selection Boards? The Civil Service Commissioners have set the pace. It is true that they have departed from orthodoxy, as the Admiralty did before them, by employing industrial psychologists in place of psychiatrists plus educational psychologists; but their pattern is the same. Is industry likely to follow their example? My guess is based on limited knowledge, but it is that progress in this direction will be slow. I know that some employers believe, rightly or wrongly, that the institution of a WOSB scheme for selecting candidates for their higher appointments would frighten off some very suitable ones. There is, I suspect, more chance of WOSB methods being used in selection for the professions, and I imagine that those who have been concerned with WOSB research and training will have explored fairly thoroughly the prospect of tackling the medical and teaching professions particularly. They are, presumably, the ones which should be most responsive. But it is rather saddening to reflect that, although the teaching profession is faced with a problem not unlike that faced by the Service departments in regard to officer-selection, nothing appears to have happened yet. This can scarcely be due altogether to anxiety about numbers, which might lead to a fear on the part of the authorities that they will have to take practically everyone who applies, because it has been made known that the present rejection rate from the ordinary boards is about 50%. The only professional group which seems to show signs of progressiveness in this matter consists of the clergy. The Anglican Church, both at home and abroad, has at least adopted the plan of having a well-organized selection “conference”, lasting a few days, at which candidates for ordination are put on trial.

In the selection of executives for industry, there is much to be said for the method developed in pre-war years by the NIIP, whereby a firm's usual selection procedure—the completion of an application form, followed by one or two interviews—was tidied up and supplemented by testing and interviewing carried out by one or two members of the National Institute's staff. I have described and discussed this in another paper, and

I will not trouble you with the details, but I want to say that it appeared to work to the satisfaction of the firms concerned. It was a one-day procedure. A group of eight or nine short-listed candidates presented themselves at the National Institute's headquarters. They were given a short explanation of the procedure and were then—as a group—put through appropriate written tests. These, and the completion of a biographical questionnaire, took up most of the morning. After an early lunch, they were interviewed, usually by two members of the NIIP staff sitting separately. The interviews normally lasted from twenty to twenty-five minutes each. By tea-time the interviewers had finished their interviews and were able to sit down to a discussion of the relative merits of the candidates and to the preparation of a short written report. This report was offered to the firm as the technical advice of an independent assessor. The final decisions were made by the firm after consideration of the report. Sometimes a representative of the National Institute was present when the company's decisions were made; more often he was not.

A good deal of work along similar lines has been done for the Royal Navy and the Royal Indian Navy in the field of officer-selection, for the Admiralty's modification of WOSB techniques has been applied only to certain large groups of officer-candidates. A penetrating discussion of it has been provided by my former colleague, Dr. N. A. B. Wilson, in a paper recently published by the NIIP. It is called "Interviewing Candidates for Technical Appointments or Training".

At this point I want to make a short comment on the relationship between psychiatrists and industrial psychologists in regard to work of this kind. For a number of reasons, including the hard fact that both psychiatrists and industrial psychologists are scarce and must almost inevitably handle a wide variety of problems, I believe that attempts to define very clearly the responsibilities of both in the personnel selection field are at present likely to be unprofitable. What is now greatly needed in the civilian sphere is the sort of intermingling which has taken place on the War Office Selection Boards, and I am quite sure that the NIIP will do its utmost to foster co-operation, not only between psychiatrists and industrial psychologists, but between both of them and other scientific workers. Before the war we had, at the National Institute, a loose but effective liaison with the Tavistock Clinic in our consulting work, and one survey of our records showed that one in every ten of those who sought vocational guidance had been advised to see a psychiatrist before making a definite choice of occupation. (The proportion among the adult applicants was a little higher, because—as one would expect—this group included a larger proportion with schizoid tendencies.) I would like to see that link strengthened appreciably by the participation of psychiatrists in the National Institute's teaching work and in its investigations in industrial organizations.

SUMMARY

First, there is clearly a great deal of personnel selection work to be done, and for several reasons it would be absurd to suggest that psychiatrists and industrial psychologists should have a direct hand in all of it. I suggest that their main function should be to help in the technical training and supervision of the non-technicians who will assuredly continue to do most of it; and of course to give assistance in the necessary research work.

Secondly, there is, in my judgment, a part to be played by both psychiatrists and industrial psychologists in the actual selection of certain groups of people, particularly for the professions and senior appointments in industry. We should not yet attempt to define very rigidly their special responsibilities; but they should both stand in a technical-advisory relationship to the employers who consult them.

Thirdly, I think it would be very unfortunate if the Ministry of Labour, or any other central organization, were persuaded to provide a personnel selection service for employers. I believe that the Ministry should aim at easing industry's personnel selection problem by the further improvement of its vocational guidance arrangements. Most of the advantages of a centralized personnel selection system might be gained by the building-up of a really good vocational guidance scheme for both young people and adults, provided that there was available also a first-rate "information service" about occupations, and provided also that we were able to work steadily—and not too slowly—towards a planned wage structure for the whole of industry. In any case, personnel selection is bound to be a negative process for those who are rejected; from the individual's point of view, vocational guidance offers a positive approach to the problem.

Fourthly, and lastly, in this vocational guidance field, as in the field of personnel selection, there is a need for both psychiatrists and industrial psychologists, not only to give assistance in the training of the vocational guidance staffs of the Ministry of Labour and certain Local Education Authorities, but also to take part in research. And, of course, if we are to make technical progress, psychiatrists and industrial psychologists must have opportunities, either official or private, for giving vocational guidance themselves.

President—Professor W. G. BARNARD, F.R.C.P.

[December 18, 1945]

DISCUSSION ON THE TOXÆMIA OF GAS GANGRENE

Mr. F. A. R. Stammers: *The surgical aspects of gas gangrene.*—Gas gangrene has long been recognized as a specific infection of devitalized muscle but it is much more important to appreciate it as a disease of circumstances. It is to the tremendous importance of these circumstances in relation to the incidence and mortality of gas gangrene that I wish to call particular attention.

Reference to the History of World War No. 1 shows that although almost nothing was known of the disease before 1914 yet much accurate knowledge was accumulated during the next two years. I will quote from it a few extracts from reports from surgeons such as Grey, Frankau and Wallace, and from pathologists such as Shaw Dunn and McNee: "Pieces of clothing carried in by shell fragments were responsible for a very large number of cases." "The disease was in the main an affection of the muscles." "The disease could in most cases be cut short by excision of muscles." "Defective blood supply is the principal cause."

The circumstances of surgery in war.—War surgery is different from any other kind of surgery, not because the soldier reacts to trauma differently from the civilian but because the circumstances under which he is wounded and under which the surgeon has to treat him are peculiar. What is right for the desert may be wrong in cultivated countries; what is possible in static warfare may be unattainable or dangerous in a war of movement; the case of six hours' standing can be treated differently from the one wounded three days previously. To put it in another way, compare the man fighting in the relatively sterile sand of the desert, dressed in shorts and an open shirt and exposed to sun, with his comrade fighting over the highly cultivated soil of North Africa and Sicily during the cold and wet winter months, his six or eight thicknesses of clothing soaked with heavily infected liquid mud; or the man in open country wounded cleanly by a sniper's bullet, with the man with his foot blown off and his calf muscles shredded up to the knee-joint through stepping on a schu-mine.

Etiology.—Gas gangrene is an infection of devitalized muscle by gas-forming organisms, though fascia, blood-clot and brain are also susceptible. The mere presence of clostridia in a wound is not sufficient—the damaged muscle is the essential thing, and major muscle wounds such as those of the buttock, thigh, calf and scapulo-axillary regions are especially liable to gas infection. Missiles such as jagged pieces of shell, mine and mortar cause more disruption of tissue than do bullets, and indriven pieces of dirty clothing or equipment are especially lethal. Anything affecting the blood supply, either directly or indirectly, encourages the disease. Thus injury to blood-vessels, tourniquets, tight bandaging, badly applied splints and ambulance journeys over rough roads all embarrass the blood supply, but the general lowering of blood-pressure resulting from hæmorrhage, shock, dehydration, exposure to wet and cold further contributes to the liability to gas gangrene. Of special significance is the observation from all fronts that something is absorbed from damaged muscle that leads to a prolonged lowering of blood-pressure, which latter will encourage gas gangrene if clostridia be present. There is a close resemblance between the case of gas gangrene toxæmia and the case of absorption of the products of lacerated muscle. Macfarlane and MacLennan in January of this year made an interim report suggesting that part of the syndrome of gas gangrene toxæmia was indeed due to the absorption of the products of breakdown of muscle resulting from clostridial infection of it.

Time is another important factor. It has been shown repeatedly that infection in wounds remains relatively superficial for the first eight to twelve hours but that after this time the deeper tissues become involved. Delay in applying surgical treatment until after this optimum interval encourages sepsis, including the risk of gas gangrene.

Symptoms and signs.—From the surgical point of view gas gangrene may present itself either as an established case (as for instance in men who could not be rescued for many hours), as an unexpected finding at first operation, or as a complication developing after the first operation—latterly a very rare event. Cases whose collection has been inevitably delayed were sometimes admitted prostrated, with cold, blue, clammy extremities, a running pulse, the wounded part being painful, swollen, livid or mottled and becoming plum-coloured from hæmelysis. Gas might or might not be present; it could often be detected with varying pressure of the stethoscope earlier or more

readily than with the fingers. If muscle was exposed it was dry and dull, and discharges were no more than an evil-smelling thin fluid. Sometimes jaundice developed.

In the case discovered unexpectedly at operation one or two affected muscles of a group, or part only of one muscle belly, with clear demarcation between normal and abnormal, are discovered during exploration of the wound. The affected muscles may be salmon pink or red, and only in extreme cases black and diffuent, and in any case they do not contract or bleed when cut. The surrounding tissues may be normal or distended with yellow œdema, and fine gas bubbles may be seen in both muscle and intermuscular septa.

In the case developing after operation the onset is sudden. There is local pain, malaise, rising temperature and pulse, and sometimes vomiting, but the outstanding and most characteristic thing is the toxæmia. From a relatively normal individual he will within an hour or so become anxious, euphoric, or wildly excited, and the pulse rapidly deteriorates. Such a case is near the end, and may turn over to reach for a drink and fall back dead in the very act. In the earlier days of the war much importance was attached to the significance of the development of pain, but during the last twelve months in Italy several surgeons remarked on the absence of pain—probably the result of better and earlier surgery, aided by penicillin.

Rather less than 50% of cases actually develop gas. One warning is called for since in the past unnecessary amputations have been performed because of the presence of emphysema. It has to be remembered that muscle fibres, cut by a sharp fragment of metal, spring apart and, like the piston of a syringe, may suck air through the skin wound into the gap. This rapidly becomes disseminated and by the inexperienced may be diagnosed as gas. The absence of toxæmia should obviate this error.

Treatment.—The essentials of treatment are surgery, blood and other intravenous fluids, and antitoxin. Generous skin incisions are needed for adequate exploration of the depth of the wound. Foreign matter, especially pieces of clothing or equipment, must be sought for and removed, and all affected muscle excised. It is best to do this by removing the complete muscle belly from origin to insertion, though in large muscles like the adductor magnus it may only be necessary to remove one part of it. All discoloured muscle and all muscle that does not bleed or contract under the knife should be removed. The deep fascia is incised longitudinally and transversely for decompression and drainage. The wound is then heavily frosted with penicillin powder and the skin is left open, being dressed with a layer of dry gauze. Enormous amounts of muscle may have to be removed—I have thrice seen all the gluteal muscles removed, with survival in two cases—and a limb may be so disorganized as to require immediate amputation, but the amputation rate is much less since better prophylactic surgery has been universally applied. These patients are always short of fluids and blood, but as the need for surgery is urgent too much time should not be spent on resuscitation: put in two pints rapidly and then take the case to the theatre with the drip still running. At the end of operation inject 100,000 units antitoxin. The intravenous drip should be continued for several days, an average of five pints daily being given. This should include one bottle of plasma daily to replenish protein and blood should be given according to hæmoglobin observations. All our forward units had a van Slyke's copper sulphate set and we always gave 15,000 units of penicillin three-hourly for about three to seven days, and although I am not at all convinced that it affected the clostridial infection I am sure that it prevented a staphylococcal infection.

I am strongly of the opinion that the treatment of gas gangrene is preventive, and by foreseeing and circumventing the adverse factors in the particular circumstances of the moment I believe that the disease can be almost eliminated. It becomes therefore a matter of organization as much as of surgical technique, and our policy in Italy was as follows:

(1) Surgical centres were so deployed that under all circumstances there was a reasonable chance that every major case would receive surgical treatment within two to six hours of wounding, and all the remainder within twelve hours. In busy centres extra surgical teams would be added. Where roads were blocked or where a minor axis was relatively isolated a Field Surgical Unit would be sent forward to work with a Field Ambulance, with instructions to operate on life-threatening conditions only—this included major muscle wounds.

(2) At the earliest possible moment all major wounds were given sufficient antitoxin to contain 8,000 units of anti-*Cl. welchii*. This was given routinely at the Advanced Dressing Station, but where evacuation to this was likely to be delayed—as in the mountains north of Florence—the antitoxin was issued to the Regimental Aid Posts.

(3) All major muscle wounds—calf, thigh, buttock and scapulo-axillary region—

were regarded as top priority cases, but even small muscle wounds were treated by careful excision too.

(4) Muscle wounds were carefully splinted at the earliest moment practicable.

(5) Because of the effect on blood-pressure of massive injury to muscle of over three hours' standing too much time was not spent on resuscitation—surgical intervention was considered the essential thing.

(6) The surgical treatment of wounds has already been described.

Dr. J. D. MacLennan: The Oxford English Dictionary defines toxæmia as a "morbid condition of the blood, caused by a toxin", and a toxin as "a specific poison, especially one produced by a microbe", and few who have watched a man die of gas gangrene can have had any doubts that these definitions were correct, and that here, in a most extreme and literal sense, was an example of bacterial blood poisoning. The fact that specific anti-sera have been shown to be of very great value in treatment lends considerable weight to this theory.

Now, at first glance, there seems to be such an overwhelming body of evidence in favour of such a view that it would be not only futile but even a little presumptuous to criticize it. Nevertheless, some recent observations which Dr. R. G. Macfarlane and I have made in the field have provided grounds for doubting whether the pathological process in man is so simple as is generally believed, whether indeed bacterial toxins as such are circulating, at all. It is this new information that I should like to bring forward.

Of the organisms causing gas gangrene in man *Cl. welchii* is by far the most important, and it is with *Cl. welchii* infections that I shall deal. As you are aware, this organism produces a whole devil's brew of toxins, and different varieties and subspecies of Welch bacillus have been described, each producing different toxins or different combinations of the same toxins. Although some of these toxins are poorly defined, and others are almost certainly still awaiting recognition, I do not think there can be any reasonable doubt that, so far as the local lesion in gas gangrene is concerned, the alpha-toxin is the component of prime importance. There is a very large volume of evidence in favour of this which need not be reviewed here, but I should particularly like to mention the recent work of Evans and of Robb-Smith. Doubtless others of the many enzymes elaborated by *Cl. welchii* must also play their part in producing the intense necrosis and peculiar tissue reactions seen in gas gangrene, but theirs must almost certainly be subsidiary roles. In view of all this, it was therefore with considerable surprise that Macfarlane and I failed to identify the alpha-toxin in the infected tissues or wound exudates (still less the blood) of 24 cases of gas gangrene due to *Cl. welchii*. It is true that in 3 cases we obtained some slight evidence of the presence of a lecithinase after twenty-four hours' incubation, but these were cases in which the tissues had been obtained post mortem and, as we have reason to believe, in these the lecithinase was produced by the multiplication of the Welch bacillus in the tissues after death.

Moreover, for reasons which we have set out in detail elsewhere, it seems improbable that these negative findings can be attributed solely to the presence of antitoxin or of phosphates, and we are forced to the conclusion that the alpha-toxin is not released into the exudates and tissue-fluids during life, because it is at once fixed by living tissues. We have not as yet been able to show that this occurs in man, but we have some evidence of its occurrence in animals (MacLennan and Macfarlane, 1945; Macfarlane and MacLennan, 1945).

It might of course be argued that the alpha-toxin is at once carried away in the blood-stream, but such experiments as we have been able to undertake are not in favour of this. First of all, we tried giving repeated small doses of toxin intravenously to rabbits, in an attempt to produce the slow absorption from infected muscle. The effect of these doses was, in every case, the appearance of intravascular hæmolysis and hæmoglobinuria. If the total dosage was sufficiently small, this hæmolysis was the only ill-effect observed. If a lethal dose was given the animal died with more or less complete intravascular hæmolysis. All these effects might be expected from the presence of a hæmolytic toxin in the blood-stream, and it is clear that given in this way, the minimum lethal dose is much larger than the minimum hæmolytic dose. When the toxic filtrate was injected intramuscularly, however, there were important differences in effects. No significant hæmolysis or hæmoglobinuria was observed, but the animal developed a fatal state of collapse and circulatory failure. The minimum lethal dose of toxin by this route, though larger than that required to kill when given intravenously, is not sufficient to produce hæmolysis.

In human gas gangrene the findings resemble those seen in rabbits injected intra-

readily than with the fingers. If muscle was exposed it was dry and dull, and discharges were no more than an evil-smelling thin fluid. Sometimes jaundice developed.

In the case discovered unexpectedly at operation one or two affected muscles of a group, or part only of one muscle belly, with clear demarcation between normal and abnormal, are discovered during exploration of the wound. The affected muscles may be salmon pink or red, and only in extreme cases black and diffident, and in any case they do not contract or bleed when cut. The surrounding tissues may be normal or distended with yellow œdema, and fine gas bubbles may be seen in both muscle and intermuscular septa.

In the case developing after operation the onset is sudden. There is local pain, malaise, rising temperature and pulse, and sometimes vomiting, but the outstanding and most characteristic thing is the toxæmia. From a relatively normal individual he will within an hour or so become anxious, euphoric, or wildly excited, and the pulse rapidly deteriorates. Such a case is near the end, and may turn over to reach for a drink and fall back dead in the very act. In the earlier days of the war much importance was attached to the significance of the development of pain, but during the last twelve months in Italy several surgeons remarked on the absence of pain—probably the result of better and earlier surgery, aided by penicillin.

Rather less than 50% of cases actually develop gas. One warning is called for since in the past unnecessary amputations have been performed because of the presence of emphysema. It has to be remembered that muscle fibres, cut by a sharp fragment of metal, spring apart and, like the piston of a syringe, may suck air through the skin wound into the gap. This rapidly becomes disseminated and by the inexperienced may be diagnosed as gas. The absence of toxæmia should obviate this error.

Treatment.—The essentials of treatment are surgery, blood and other intravenous fluids, and antitoxin. Generous skin incisions are needed for adequate exploration of the depth of the wound. Foreign matter, especially pieces of clothing or equipment, must be sought for and removed, and all affected muscle excised. It is best to do this by removing the complete muscle belly from origin to insertion, though in large muscles like the adductor magnus it may only be necessary to remove one part of it. All discoloured muscle and all muscle that does not bleed or contract under the knife should be removed. The deep fascia is incised longitudinally and transversely for decompression and drainage. The wound is then heavily frosted with penicillin powder and the skin is left open, being dressed with a layer of dry gauze. Enormous amounts of muscle may have to be removed—I have thrice seen all the gluteal muscles removed, with survival in two cases—and a limb may be so disorganized as to require immediate amputation, but the amputation rate is much less since better prophylactic surgery has been universally applied. These patients are always short of fluids and resuscitation: put in two pints rapidly and then take the case to the theatre with the drip still running. At the end of operation inject 100,000 units antitoxin. The intravenous drip should be continued for several days, an average of five pints daily being given. This should include one bottle of plasma daily to replenish protein and blood should be given according to hæmoglobin observations. All our forward units had a van Slyke's copper sulphate set and we always gave 15,000 units of penicillin three-hourly for about three to seven days, and although I am not at all convinced that it affected the clostridial infection I am sure that it prevented a staphylococcal infection.

I am strongly of the opinion that the treatment of gas gangrene is preventive, and by foreseeing and circumventing the adverse factors in the particular circumstances of the moment I believe that the disease can be almost eliminated. It becomes therefore a matter of organization as much as of surgical technique, and our policy in Italy was as follows:

(1) Surgical centres were so deployed that under all circumstances there was a reasonable chance that every major case would receive surgical treatment within two to six hours of wounding, and all the remainder within twelve hours. In busy centres extra surgical teams would be added. Where roads were blocked or where a minor axis was relatively isolated a Field Surgical Unit would be sent forward to work with a Field Ambulance, with instructions to operate on life-threatening conditions only—this included major muscle wounds.

(2) At the earliest possible moment all major wounds were given sufficient anti-toxin to contain 8,000 units of anti-*Cl. welchii*. This was given routinely at the Advanced Dressing Station, but where evacuation to this was likely to be delayed—as in the mountains north of Florence—the antitoxin was issued to the Regimental Aid Posts.

(3) All major muscle wounds—calf, thigh, buttock and scapulo-axillary region—

The statistical data obtained established in principle that the use of antitoxin gives a patient a better chance of recovery, but in the field antitoxin appears to be almost as essential as surgery for a good recovery rate. In the various campaigns of the British Army the recovery rate from gas gangrene ran parallel to the proportion of the cases receiving early and adequate treatment in addition to surgical treatment (MacLennan and Macfarlane, 1944). The rise in the mean recovery rate for all cases, from 30% in Sicily to 70 to 75% in the later stages of the Italian campaign and in the B.L.A., was substantially due to the wider and intensive use of antitoxin, and not simply to a general improvement in the conditions, or any attenuation of the disease; for the recovery rate amongst those receiving adequate antitoxin therapy showed a relatively slight improvement (from 65 to 75%) over the same period, in spite of better military conditions, experienced surgeons and the introduction of penicillin. The fact that with the best treatment possible the death-rate remained about 25% indicates, however, the existence of another cause of toxæmia in addition to the bacterial toxin (Macfarlane, 1945).

From the biochemical point of view, several causes of the toxæmia of gas gangrene seem possible. (1) *Action of the bacterial toxin on a vital organ: Cl. welchii* toxin contains a lecithinase which is probably identical with the alpha-toxin (Macfarlane and Knight, 1941). The interest of this enzyme lies in the physiological significance of lecithin, particularly in relation to the permeability of the cell membrane. From analysis of different fractions of rabbit muscle it appears that lecithin is associated with myosin, the contractile protein in the fibril, as well as with the sarcolemma. It seems possible that the fibril is invested with a lipid layer which prevents the diffusion from the fibril of substances, such as adenosine-triphosphate and phosphocreatine, necessary for the cycle of contraction, and that it is the destruction of this layer by the bacterial lecithinase which leads to the uniform staining of the fibril and the early loss of contractility noted by McNee and Shaw Dunn (1917). Toxæmia or death may therefore be due to the loss of contractility of cardiac muscle, before any gross change in the heart is visible. (2) *Production of a toxic substance by infecting organisms*: So long as infected tissue remains in the body, the possibility that the toxæmia is due in part to immunologically non-specific substances must be borne in mind. *Cl. welchii*, for instance, produces histamine from histidine, so that the conjunction of this organism with a proteolytic organism might give a different picture from that in an experimental infection with *Cl. welchii* alone. (3) *Toxæmia due to ischæmic muscle*: In a large proportion of the cases, gas gangrene arose in muscles with a damaged blood supply; in addition, traumatic or hæmorrhagic shock sustained at the time of the injury presumably contributes to an anoxæmia which causes further tissue damage. After the occurrence of renal failure, similar to that seen in the crush syndrome, had been reported (Jeffrey and Scott Thomson, 1944) some biochemical investigations on the nature of this toxæmia were planned. Specimens of muscle from cases of gas gangrene and of vascular gangrene amongst the B.L.A. casualties were received from Major MacLennan; comparison of the chemical analyses with that of normal muscle showed that both in the gangrenous and in ischæmic muscle a marked loss of adenyly compounds, creatine and potassium had taken place. The loss of potassium is of interest in view of Rosenthal's work on the electrolyte balance in experimental shock, and the fact that, in incipient shock, the lethal dose of potassium is decreased to about one-eighth of the normal dose (Tabor and Rosenthal, 1945). It seems very probable that local changes due to an increased permeability of the cell membrane, whether caused by the bacterial toxin or by anoxæmia, play an important part in the development of the toxæmia of gas gangrene.

Sir Percival Hartley and Dr. D. G. Evans: As a result of the war, the Department of Biological Standards at the National Institute for Medical Research, Hampstead, became responsible for the supply of the international standards for the gas gangrene antitoxins (Hartley, 1945). Two of these had originally been prepared at Hampstead (Hartley, 1931; Hartley and Bruce White, 1935) and replacement standards for three of them were made during the war (Hartley and Evans, 1942 '3). Shortly after the outbreak of war doubts were expressed as to the adequacy of the international standard for *Cl. welchii* Type A antiserum; it was argued that while the standard provided for the assay of a antitoxin other activities of the organism, such as its power to produce hæmolysin and hyaluronidase, and the bearing of these on infection and of the corresponding antibodies in the

muscularly, rather than in those injected intravenously. Even in rapidly fatal cases, who have received no antitoxin, it is exceptional to observe hæmoglobinæmia or hæmoglobinuria. Indeed, throughout the whole war, I have myself seen only 3 such cases and know of a total of not more than 7. All appear to have been associated with a true *Cl. welchii* septicæmia.

The question at once arises, what is this toxic factor? There seem to be two main possibilities. It may be that the traditional view is correct and that bacterial toxins are seeping into the circulation from the infected tissues, perhaps even the alpha-toxin itself; for it is conceivable that if it reaches the blood-stream in small amounts it might not cause obvious hæmolysis, and yet by localizing in vital centres—the C.N.S. is particularly rich in lecithins for example—gradually build up a concentration sufficient to cause irreparable cell-damage. Indeed, if a bacterial toxin is involved, it seems most likely to be the alpha-toxin, for both the experimental work and the clinical experience of this war have shown that the value of *Cl. welchii* therapeutic antiserum lies primarily in its anti-alpha-toxin content.

There is, however, one serious drawback to this view. Experimentally we have shown that in adequate dosage *Cl. welchii* anti-serum will protect rabbits from the intravenous inoculation of lethal doses of *Cl. welchii* filtrate, but this is certainly not always true of the natural muscle infection. We made antitoxin titrations in 28 cases of gas gangrene, and found that the presence of an excess of antitoxin in the blood-stream and wound area will not necessarily prevent a fatal outcome. Moreover, the only fatal cases in this series were those in whom the surgeons had failed to remove all the infected tissue; and this at once suggests the second, and to me attractive possibility, that a non-hæmolytic toxic factor, not neutralized by antitoxin, may be derived from disintegrating muscle.

The implications of such a theory are obvious—it would link up the shock-like prostration of gas gangrene with the very similar condition resulting from severe trauma, and possibly also with the crush-syndrome and related states.

In conclusion I should like to stress one point. It has been suggested that these latest findings of ours make clear the worthlessness of serum treatment in gas gangrene. Nothing could be further from the facts. Personally, having dealt with little else than gas gangrene and related conditions for the active period of the war, I have not the slightest doubt of the value of antiserum both in prophylaxis and treatment. When I first saw large numbers of cases in 1940, our mortality rate was well over 50%—since 1942 (apart from a bad patch in Sicily) it has been below 30% and all the evidence relates this considerable drop in fatality to the introduction of a more intensive serotherapy. Moreover, since then, neither larger doses of serum, nor more active sulphonamides, nor the flavines, nor penicillin itself has in any way reduced this final hard core of cases sure to die.

The real questions at issue therefore seem to me to be:

(1) Is there more than one form of toxæmia in gas gangrene? One—the usual form, rarely seen now, directly related to the bacterial toxins; the other, forming most of our irreducible 30%, produced by other factors, possibly derived from tissues.

(2) That being decided—why does death occur and how can we prevent it?

To neither of these questions are we at present in a position to give an answer.

Dr. Marjorie Macfarlane: The existence of a bacterial toxæmia in clinical gas gangrene has been doubted because of the failure to detect the toxin in blood samples from the patient. Evidence that the toxin is absorbed from the local lesion has, however, been furnished by the beneficial effect of antitoxin on the recovery rate from gas gangrene in the late war. An analysis of cases reported on Army Form I.1241 (Macfarlane, 1943) showed that in the group of patients who underwent amputation within six hours of diagnosis of the disease, the death-rate was significantly and substantially lower amongst those who also received antitoxin within this time, compared with those who received no antitoxin or only received it at a late stage of the disease. Since this antitoxin was usually given at the time of amputation, i.e. when the affected tissue and the source of the toxin had been eradicated, its beneficial effect is only explicable on the basis that it neutralized the specific toxin which had been acting after absorption as a systemic poison.

The statistical data obtained established in principle that the use of antitoxin gives a patient a better chance of recovery, but in the field antitoxin appears to be almost as essential as surgery for a good recovery rate. In the various campaigns of the British Army the recovery rate from gas gangrene ran parallel to the proportion of the cases receiving early and adequate treatment with antitoxin in addition to surgical treatment (MacLennan and Macfarlane, 1944). The rise in the mean recovery rate for all cases, from 30% in Sicily to 70 to 75% in the later stages of the Italian campaign and in the B.L.A., was substantially due to the wider and intensive use of antitoxin, and not simply to a general improvement in the conditions, or any attenuation of the disease; for the recovery rate amongst those receiving adequate antitoxin therapy showed a relatively slight improvement (from 65 to 75%) over the same period, in spite of better military conditions, experienced surgeons and the introduction of penicillin. The fact that with the best treatment possible the death-rate remained about 25% indicates, however, the existence of another cause of toxæmia in addition to the bacterial toxin (Macfarlane, 1945).

From the biochemical point of view, several causes of the toxæmia of gas gangrene seem possible. (1) *Action of the bacterial toxin on a vital organ: Cl. welchii* toxin contains a lecithinase which is probably identical with the alpha-toxin (Macfarlane and Knight, 1941). The interest of this enzyme lies in the physiological significance of lecithin, particularly in relation to the permeability of the cell membrane. From analysis of different fractions of rabbit muscle it appears that lecithin is associated with myosin, the contractile protein in the fibril, as well as with the sarcolemma. It seems possible that the fibril is invested with a lipid layer which prevents the diffusion from the fibril of substances, such as adenosine-triphosphate and phosphocreatine, necessary for the cycle of contraction, and that it is the destruction of this layer by the bacterial lecithinase which leads to the uniform staining of the fibril and the early loss of contractility noted by McNee and Shaw Dunn (1917). Toxæmia or death may therefore be due to the loss of contractility of cardiac muscle, before any gross change in the heart is visible. (2) *Production of a toxic substance by infecting organisms*: So long as infected tissue remains in the body, the possibility that the toxæmia is due in part to immunologically non-specific substances must be borne in mind. *Cl. welchii*, for instance, produces histamine from histidine, so that the conjunction of this organism with a proteolytic organism might give a different picture from that in an experimental infection with *Cl. welchii* alone. (3) *Toxæmia due to ischæmic muscle*: In a large proportion of the cases, gas gangrene arose in muscles with a damaged blood supply; in addition, traumatic or hæmorrhagic shock sustained at the time of the injury presumably contributes to an anoxæmia which causes further tissue damage. Sir Percival Hartley and Dr. D. G. Evans: As a result of the war, the Department of Biological Standards at the National Institute for Medical Research, Hampstead, became responsible for the supply of the international standards for the gas gangrene antitoxins (Hartley, 1945). Two of these had originally been prepared at Hampstead (Hartley, 1931; Hartley and Bruce White, 1935) and replacement standards for three of them were made during the war (Hartley and Evans, 1942/3). Shortly after the outbreak of war doubts were expressed as to the adequacy of the international standard for *Cl. welchii* Type A antiserum; it was argued that while the standard provided for the assay of a antitoxin other activities of the organism, such as its power to produce hæmolysin and hyaluronidase, and the bearing of these on infection and of the corresponding antibodies in the

control of the disease, had not been taken into account and provided for. As custodians of the international standard preparations we regarded this as a serious criticism because, if these antibodies were important in the control of the disease, they should be provided in the antiserum in adequate amounts and measured by reference to a more complete standard, or to a series of standards which, it was claimed, should be provided. Accordingly, following an important conference at Cambridge on April 5, 1941, at which this question was discussed, investigations have been carried out at Hampstead with the object of determining the relative importance of the various antigens on the causation, and of the antibodies to these occurring in *Cl. welchii* Type A antiserum in the prevention and treatment, of gas gangrene. Thanks to the co-operation of our friends at the Wellcome Physiological Research Laboratories at Beckenham, who have generously supplied us with the necessary specific antibody preparations, it has been possible to study the effect of these separate antibodies on the prevention of gas gangrene, and on the course of the disease, in experimentally infected guinea-pigs.

Evans (1943a) showed that a small dose of α antitoxin (free from θ antihæmolysin) given four hours before a dose of *Cl. welchii* A which produced θ hæmolysin and which proved fatal to unprotected guinea-pigs, afforded complete protection; the largest dose of θ anti-hæmolysin which could be administered, however, gave no protection whatever. Later in the same year (1943b) Evans showed that complete protection was afforded by a small dose of α antitoxin (free from antihyaluronidase) against a fatal infection produced by strains of *Cl. welchii* A which produced hyaluronidase: while antiserum containing antihyaluronidase (but free from α antitoxin) afforded no protection and failed to affect the course of the disease in guinea-pigs. Later, antisera containing larger quantities of θ antihæmolysin and antihyaluronidase respectively became available and it was shown that larger doses of these antibodies neither protected against the disease nor enhanced the protective value of α antitoxin. In a study of 30 strains of *Cl. welchii* A, Evans (1945a) showed that there was a close correlation between the power to produce α toxin in culture and virulence, while no such correlation could be demonstrated for hæmolysin or for hyaluronidase; further, he showed that complete protection against infection against 28 of these strains was afforded by a small dose (25 units) of α antitoxin. One strain, however, required 100, and another 200, units of α antitoxin for protection. The importance of α antitoxin is clearly brought out in these experiments and the results are of special interest in relation to the findings of Weinberg and Guillaumie (1938). Evans (1945b) has also shown that small doses of α antitoxin, free from anti-collagenase, afforded complete protection to guinea-pigs infected with strains of *Cl. welchii* A, which produced collagenase, while preparations of antiserum containing anticollagenase (and no α antitoxin) neither protected guinea-pigs nor enhanced the protective value of α antitoxin itself. In another series of experiments (1945c) Evans has shown that specific antitoxin administered intravenously after infection with *Cl. welchii* A, *Cl. œdematians* or *Cl. septicum* has a marked clinical effect on the course of the disease in guinea-pigs; and, although antitoxin could not influence the development of the lesions produced by the action of toxin on local tissue yet life was prolonged, especially if treatment had not been unduly delayed. Given early in the disease, the toxæmia was controlled, the power of the organism to proliferate was apparently restricted and the natural defence and recovery mechanisms of the guinea-pig came into operation; under certain conditions of experiment the animals recovered completely. In another experiment in which infection, ending fatally in untreated guinea-pigs, was established with a strain which produced collagenase, Evans (1945b) showed that small doses of α antitoxin (free from anti-collagenase) given four hours after infection had a marked effect on the course of the disease; and it was also shown that no significant difference in results was obtained whether the antitoxin was given intravenously or directly into the infected muscle. One other experiment was described which illustrated the importance of early surgery in the treatment of gas gangrene infections. Two exactly similar groups of guinea-pigs, 18 in each group, were injected with a virulent strain of *Cl. welchii* A. One group received no treatment whatever and all the 18 animals died within three days; four hours after infection an incision was made into the infected thigh muscle of each of the 18 animals of the second group, and in this case 13 animals survived for more than fourteen days and, of the 5 which died, life was prolonged to four and five days in three of these.

President—A. DICKSON WRIGHT, M.S., F.R.C.S.

[November 9, 1945]

Thiouracil Agranulocytosis: Recovery on Pyridoxine.—HERMON TAYLOR, M.D., M.Ch., F.R.C.S. Demonstrated by C. H. de Boer, M.B., B.Chir.

24.8.45: Mrs. J. D., aged 49, attended London Hospital with a moderate degree of thyrotoxicosis; ambulatory treatment with thiouracil, 100 mg. b.d. Toxic symptoms disappeared during ensuing six weeks; W.B.C. remained between 5,000 to 7,000; polymorphs 60%. Dosage reduced to 75 mg. thiouracil b.d. for next three weeks.

16.10.45: First abnormal count. W.B.C. 3,500; 50% polymorphs.

19.10.45: Thiouracil discontinued (total dose to date 10 grammes).

21.10.45: Patient felt ill, sore throat. W.B.C. 1,400; 4% polymorphs.

24.10.45: Admitted to hospital T. 102-6, P. 96. Flushed, ill, inflamed fauces.

25.10.45: Condition worse; fauces and pharynx covered with white patches (treated by gentian violet). W.B.C. 600; 3% polymorphs (18 polymorphs per c.mm.). Sternal marrow smear showed complete absence of all granulocytes. Blood transfusion given.

27.10.45: Jaundiced. Patient almost comatose, could be roused with difficulty. Passed no urine in twenty-four hours. Pyridoxine (vitamin B₆) therapy commenced on the advice of Professor Marrack; 150 mg. per day given intravenously.

28.10.45: W.B.C. 1,000.

29.10.45: Patient improved; less apathetic; throat less sore; could swallow soft solids for the first time. W.B.C. 3,000; 22% polymorphs.

30.10.45: Better. W.B.C. 6,600; 38% polymorphs.

31.10.45: Much better. W.B.C. 13,300; 71% polymorphs.

1.11.45: Sternal marrow smear now showed regeneration of granulocytes (*see Table*).

3.11.45: Patient convalescent. W.B.C. 23,800; 83% polymorphs. Red cell and platelet counts had remained materially unchanged throughout.

control of the disease, had not been taken into account and provided for. As custodians of the international standard preparations we regarded this as a serious criticism because, if these antibodies were important in the control of the disease, they should be provided in the antiserum in adequate amounts and measured by reference to a more complete standard, or to a series of standards which, it was claimed, should be provided. Accordingly, following an important conference at Cambridge on April 5, 1941, at which this question was discussed, investigations have been carried out at Hampstead with the object of determining the relative importance of the various antigens on the causation, and of the antibodies to these occurring in *Cl. welchii* Type A antiserum in the prevention and treatment, of gas gangrene. Thanks to the co-operation of our friends at the Wellcome Physiological Research Laboratories at Beckenham, who have generously supplied us with the necessary specific antibody preparations, it has been possible to study the effect of these separate antibodies on the prevention of gas gangrene, and on the course of the disease, in experimentally infected guinea-pigs.

Evans (1943a) showed that a small dose of a antitoxin (free from θ antihæmolyisin) given four hours before a dose of *Cl. welchii* A which produced θ hæmolyisin and which proved fatal to unprotected guinea-pigs, afforded complete protection; the largest dose of θ anti-hæmolyisin which could be administered, however, gave no protection whatever. Later in the same year (1943b) Evans showed that complete protection was afforded by a small dose of a antitoxin (free from antihyaluronidase) against a fatal infection produced by strains of *Cl. welchii* A which produced hyaluronidase; while antiserum containing antihyaluronidase (but free from a antitoxin) afforded no protection and failed to affect the course of the disease in guinea-pigs. Later, antisera containing larger quantities of θ antihæmolyisin and antihyaluronidase respectively became available and it was shown that larger doses of these antibodies neither protected against the disease nor enhanced the protective value of a antitoxin. In a study of 30 strains of *Cl. welchii* A, Evans (1945a) showed that there was a close correlation between the power to produce a toxin in culture and virulence, while no such correlation could be demonstrated for hæmolyisin or for hyaluronidase; further, he showed that complete protection against infection against 28 of these strains was afforded by a small dose (25 units) of a antitoxin. One strain, however, required 100, and another 200, units of a antitoxin for protection. The importance of a antitoxin is clearly brought out in these experiments and the results are of special interest in relation to the findings of Weinberg and Guillaumie (1938). Evans (1945b) has also shown that small doses of a antitoxin, free from anti-collagenase, afforded complete protection to guinea-pigs infected with strains of *Cl. welchii* A, which produced collagenase, while preparations of antiserum containing anticollagenase (and no a antitoxin) neither protected guinea-pigs nor enhanced the protective value of a antitoxin itself. In another series of experiments (1945c) Evans has shown that specific antitoxin administered intravenously after infection with *Cl. welchii* A, *Cl. œdematiens* or *Cl. septicum* has a marked clinical effect on the course of the disease in guinea-pigs; and, although antitoxin could not influence the development of the lesions produced by the action of toxin on local tissue yet life was prolonged, especially if treatment had not been unduly delayed. Given early in the disease, the toxæmia was controlled, the power of the organism to proliferate was apparently restricted and the natural defence and recovery mechanisms of the guinea-pig came into operation; under certain conditions of experiment the animals recovered completely. In another experiment in which infection, ending fatally in untreated guinea-pigs, was established with a strain which produced collagenase, Evans (1945b) showed that small doses of a antitoxin (free from anti-collagenase) given four hours after infection had a marked effect on the course of the disease; and it was also shown that no significant difference in results was obtained whether the antitoxin was given intravenously or directly into the infected muscle. One other experiment was described which illustrated the importance of early surgery in the treatment of gas gangrene infections. Two exactly similar groups of guinea-pigs, 18 in each group, were injected with a virulent strain of *Cl. welchii* A. One group received no treatment whatever and all the 18 animals died within three days; four hours after infection an incision was made into the infected thigh muscle of each of the 18 animals of the second group, and in this case 13 animals survived for more than fourteen days and, of the 5 which died, life was prolonged to four and five days in three of these.

right hypochondrium. He had been constipated for a few days previously. The pain was continuous with no relief, causing nausea and repeated vomiting. He was admitted to hospital and later transferred to the London Hospital.

May 3, 1945 on admission, he was pale, ill-looking and in pain, occasionally retching with small vomits of bile-stained fluid. Jaundiced sclerotics. Tongue was furred. Slight general wasting and dehydration. Temperature 100°; pulse 100; respiration 24.

Abnormal physical signs.—Respiratory system: Lower right ribs prominent. Movement—right greater than left in lower part. P.N. dull at right base. Breath sounds; occasional rhonchi at right base. Liver enlarged upwards.

Abdomen: Liver tender and enlarged 2 fingerbreadths. Small "stab wound" scar in mid-epigastric region (site of abscess drainage).

C.V.S. and C.N.S. apparently normal.

Diagnosis.—Amœbic hepatitis with recurrent abscess.

Investigations.—Blood: Granulocytosis (leucocytes 21,200, polys. 92%), Hb. 102%. Stools: No amœbæ or cysts seen. No R.B.C. Van den Bergh reaction: Qualitative—biphasic reaction. Quantitative—4 mg. of bilirubin per 100 c.c. Alkaline phosphatase 12 units (normal 6 to 10 units). X-ray of chest: Slight increase of lung markings in right mid-zone. Right side of diaphragm raised and liver margin depressed.

Treatment and progress.—He was put on a high protein, low fat, low residue diet with extra glucose and fluids. Kapilon 20 mg. daily, Ascorbic acid 25 mg. b.d. and a course of emetine hydrochloride 1 grain daily started. There was no response to this. Attempted aspirations produced pure blood only—culture sterile. His general condition remained about the same.

He was seen by Sir Philip Manson-Bahr who reported:

"There is no doubt about the diagnosis in this case. There is a large liver abscess subdiaphragmatic in the posterior part of the right lobe of the liver. It ascends to the 7th rib on the scapular line.

"There is a marked pleuritic rub which indicates that the abscess is about to rupture into the pleura at the angle of the right scapula. I suggest that this is primarily an amœbic abscess which has recurred after two years and that the pus is now secondarily infected with some micro-organism.—? *B. coli* or *B. endometritidis*."

On his advice rib resection and exploration of the liver were carried out through a transpleural approach. A small amount of thick pus was encountered. Further exploration to isolate cavity was unsuccessful; assumed to be many small cavities.

Subsequent chest X-ray showed hydropneumothorax.

Culture from aspirated fluid—profuse growth of *Staphylococcus pyogenes*, sensitive to penicillin.

A five-day course of penicillin (total 553,000 units) resulted in slight improvement. Jaundice was less. Pyrexia continued with occasional rigors.

Further swab showed growth of aerobic and anaerobic *B. coli*, sensitive to sulphathiazole.

A combined course of sulphamezathine 30 grammes and penicillin 720,000 units was given followed by a twelve-day course of emetine bismuth iodide 1 grain t.d.s., then carbazone 0.25 mg. b.d. for ten days.

Subsequent progress was satisfactory. He remained afebrile. Normal pulse. No rigors. Gained weight. No amœbæ or cysts seen in three stool reports.

Drainage-wound healed well. X-ray of chest showed complete re-expansion of lung; no pleural effusion.

[December 14, 1945]

Primary Splenic Granulocytopenia and Lymphopenia.—HERBERT LEVY, M.D., M.R.C.P.

Emily O., aged 69. Admitted to hospital May 1945 for conjunctivitis. Deformity of fingers since about age of 56; has been living in L.C.C. Institutions ever since. Typhoid fever about twenty years ago.

On examination.—Rather frail; somewhat poor mental power; not looking ill. Iritis and conjunctivitis; corneal nebulae. Spleen 5 in. below costal margin, reaching nearly mid-line and lower pole about midway between levels of umbilicus and symphysis pubis. Small axillary and inguinal lymph nodes. Liver 1½ in. below costal margin. Moderate degree of lower dorsal kyphosis. Arteriosclerosis of peripheral vessels. Calcified uterine fibroid. Skiagram of chest: increased striation of all lung fields; right diaphragm higher than left.

Flexion deformity of both little fingers in proximal interphalangeal joint; hyperextension of distal interphalangeal joints. Undue mobility of interphalangeal joint of thumbs; in

Comment.—The use of pyridoxine in the treatment of agranulocytosis was first suggested by Cantor and Scott in 1944 following a report of the occurrence of a leucocytosis in cases of anaemia treated with vitamin B₆.

Previous to 1931 the treatment of this condition was by: elimination of the cause, if known, and repeated blood transfusions whose value is doubted. In 1931 pentnucleotide was introduced to stimulate the release of the myeloid cells. Jackson and Tighe (1939) reported a reduction of the mortality to 30% from its use; Fettes and Whitby (1935) had less success. Jackson showed that it had little effect where there is aplasia of the marrow. In 1938 some help was gained from the use of bone-marrow concentrates for agranulocytosis when pentnucleotide had failed, but this has not been fully confirmed. Fatal toxic reactions to thiouracil are not common, 1% of 600 published cases. When agranulocytosis occurs, however, it is associated with marrow atrophy and is rapidly fatal in spite of transfusion and pentnucleotide. It is suggested that pyridoxine intravenously may restore the marrow function even at a late stage in the disease.

POSTSCRIPT (19.11.45).—The patient was given another course of pyridoxine, 50 mg. per day for four days, intravenously. This had no effect whatsoever on her total white or differential count.

Hepatitis with Abscess Secondarily Infected by *Staphylococcus pyogenes* and *B. coli*.— R. G. BIRD, M.B.

This soldier, W. W., aged 37, was transferred to the London Hospital on 3.5.45 complaining of sharp pains in the right upper abdomen.

History.—Passed A 1 into the Army on September 12, 1940, having had no previous serious illness. He remained well until June 1941 when, during the first two weeks of being in Africa, he had attacks of nausea and diarrhoea with frequent fluid stools—no blood, no mucus. Without treatment he became symptom-free, remaining so (except for a mild attack of bronchopneumonia in January 1943) until October 1943 when a very bad attack of symptoms as in June 1941 occurred and he was admitted to hospital in Cairo. Amoebic dysentery was diagnosed. A full course of emetine treatment was given, during which a lump appeared in the right epigastric area. He was told it was an amoebic abscess. It was aspirated thirteen times. He remained in this hospital five months.

By February 1944 he appeared well again and was repatriated. Given convalescent leave, then in April discharged from hospital, category C 2, recommended for light duties for six months.

Apart from occasional vague epigastric discomfort at night, he remained symptom-free until April 1945 when, while on leave, he was suddenly seized by sharp, gnawing pain in

Blood-counts.—

1945	July 9	July 17	July 31	Aug. 3	Sept. 20	Dec. 12

Monos. ...	584	696	852	852	207	1,040

Most of the lymphocytes have either an immature (abnormally basophil) cytoplasm or a nucleus of the Rieder cell type or an immature nucleus, many cells having also an abnormally large amount of, often coarse, azure granules.

Sternal marrow count: Cells of myeloid series 54.46% out of which 14.84% eosinophils; 1% lymphoblasts; 30% lymphocytes; 2.5% plasma cells; 11.83% nucleated R.B.C.; 0.16% Ferrata cells. Out of 600 cells only two, both erythroblasts, were in mitosis. A few of the band-shaped neutrophils were abnormally large. Lymphocytes in bone-marrow had same appearances as those in peripheral blood.

August 1945: Serum—cholesterol 184 mg.%, protein 7.8 grammes%, albumin 4.1 grammes%, globulin 3.7 grammes%, uric acid 3.3 mg.%. .

December 1945: Glucose tolerance test (50 grammes orally):

Fasting blood sugar	100 mg.%
30 min. after glucose administration	218
60 " " "	"	"	159, no glycosuria
90 " " "	"	"	123
120 " " "	"	"	104, no glycosuria
150 " " "	"	"	70

Biopsy of skin: "Strongly in favour of a (malignant) reticulosis; the sections are not consistent with a dermatitis, eczema, or psoriasis, conditions clinically indistinguishable from that of your patient" (W. Freudenthal).

Biopsy of inguinal lymph node: "Largely a reactive change of the lipomelanotic reticulosis type, but there are in the medulla clumps of atypical lymphoid cells whose nature it is difficult to determine and the same is true with regard to the foci of the lymphoid proliferation in the superficial dermis; in this case the skin changes are more marked than I have seen before and so there is a possibility that it is associated with a primary blood disease but I am a bit sceptical about it and believe that it does correspond to this group [lipomelanotic reticulosis] of conditions" (A. H. T. Robb-Smith).

General condition now rather better than in summer months. Exfoliation recently much diminished; skin red to dusky red, rather purple over lower back; texture as before ("elephant skin"). Afebrile and not confined to bed.

For permission to demonstrate the patient I wish to thank Dr. B. Young, Medical Superintendent, St. Alfege's (L.C.C.) Hospital, under whose care he now is. For the peripheral blood-counts and biochemical tests I am obliged to Drs. R. F. L. Hewlett and E. N. Allott.

Comment.—When first confronted with this case, the problem was: is the erythrodermia a manifestation of a lymphatic leukaemia or of a Hodgkin or are the lymph-node enlargements secondary to the skin affection? A certain bias in favour of lymphatic leukaemia began to wane after seeing the peripheral blood film. The sternal marrow picture made the possibility of a leukaemia still less likely; while about 25% lymphocytes are the upper normal limit, a finding of 30% does not yet allow the diagnosis of lymphatic leukaemia unless this is based on other evidence; and the rather high eosinophilia (subsequently also found in the peripheral blood) pointed towards reactive change or Hodgkin. The various abnormalities of the lymphocytes also favoured the probability of a lymphatic reaction rather than of a leukaemia. Hodgkin's disease could definitely be excluded by the lymph-node biopsy, and Dr. Robb-Smith's opinion regarding leukaemia is quoted above. On looking more closely through the literature of cases of this kind reported as lymphatic, or in the last two decades quite often as monocytic leukaemia, there seems little doubt that this diagnosis stands in at least a good number of cases on rather weak legs. In the

resting position the phalanges stand to each other in hyperextension. Ulnar deflection of second to little fingers of both hands. Halluces valgi. Some toes in hammertoe position. Skiagram of hands: bony ankylosis of proximal interphalangeal joints of both little fingers; spaces of other joints in normal limits and no periarticular atrophy or sclerosis of bone.

Blood-counts.—

1945	May 15	May 16	July 18	Aug. 24	Oct. 3	Nov. 9
R.B.C. (millions)	3.91	3.99	4.4	4.23	4.52	
Hb. (Haldane) ...	82	82	74	85	86	
W.B.C. ...	1,000	900	1,200	770	500	1,750

Eosinos.	40	36	—	8	15	52
Basos. ...	20	—	—	—	—	—
Lymphos. ...	620	468	612	616	340	998
Monos. ...	120	180	96	23	60	87

Platelets normal in appearance; numbers low on one occasion but within normal limits on all other occasions.

16.5.45: M.C.V. 92 cu. μ . M.C.Hb. concentration 33%.

Sternal marrow: very active erythropoiesis and myelopoiesis; erythroblasts of normal, non-megaloblastic series. Megakaryocytes rather abundant. No other quantitative or qualitative abnormality noted.

Serum—protein 6.4 grammes%, albumin 3.7 grammes%, globulin 2.7 grammes%, bilirubin 0.2 mg.%, phosphatase (alkaline) 7.5 units. Takata-Ara and formol gel: both positive, moderately strong. Blood urea 38 mg.%. Serum cholesterol 178 mg.%.

Pyridoxine hydrochloride was given intravenously: 150 mg. on December 8 and 9, and 100 mg. on December 11, 12, and 13. Subsequent blood-counts:

1945	Dec. 10	Dec. 12	Dec. 14
W.B.C. ...	2,450	1,725	1,275
Polys.: Neutros. ...	490	259	128
Eosinos. ...	220	138	102
Basos. ...	25	17	—
Lymphos. ...	1,543	1,156	892
Monos. ...	172	155	153

No change in general condition since under observation. The increase in eosinophil polymorphs and lymphocytes at the time of the pyridoxine treatment was possibly related to a recent flare-up of the iritis.

For the peripheral blood-counts and biochemical tests I am obliged to Dr. J. M. Alston.

Generalized Erythrodermia (? Malignant Reticulosis).—HERBERT LEVY, M.D., M.R.C.P.

William J., aged 70. Past and family history irrelevant. About 1939 red, itchy rash over middle of chest which was gradually spreading, losing at the same time its pruriginous character; surface of whole body involved by about 1944. Admitted to hospital May 1945 for carbuncle of neck. Irregular intermittent pyrexia up to 101° during May 1945; later on occasional bouts of fever subsiding in a few hours. July 1945 a few pyodermic lesions.

On examination (July 1945).—Generalized erythrodermia, with bran-like exfoliation especially on face and scalp and considerable thickening and stiffness of entire skin. Gross dystrophy of all nails; visibly enlarged inguinal lymph nodes, cervical and axillary lymph nodes up to cherry-stone or date-stone size. Tongue and visible mucous membranes normal in appearance except for marked injection of palpebral conjunctivae. Spleen not palpable; liver slightly enlarged.

He was discharged on July 18, 1945, with regular rhythm and normal rate and was put on a maintenance dose of quinidine sulph. 3 grains b.d. He felt well until September 1945 when tachycardia recurred and he was readmitted to Guy's Hospital on September 9, 1945; paroxysmal auricular tachycardia with 2:1 block again was found. Alternation in cycle length of the P-P intervals was marked (see fig. 1) (Barker, Johnston and Wilson, 1943). Tinct. digitalis m xv , q.i.d. given during two and a half days, abolished the attack and on September 28, 1945, a ventricular rate of 65 with regular rhythm was recorded. A maintenance dose of tinct. digitalis m vii once daily produced coupling owing to ventricular extrasystoles. With quinidine sulph. 3 grains six times a day, started on October 10, regular rhythm (rate 60-70) persisted until October 21 when both ventricular and pulse-rates rose to about 128. Electrocardiograms (October 22, 23 and 24) showed recurrence of paroxysmal auricular tachycardia; the ventricular rhythm being a little faster than *half* the auricular rate there was occasional interference with the ventricular rhythm by conducted auricular beats: dissociation with interference. Most of the features known to occur in the ordinary form of dissociation with interference (in which a faster atrioventricular rhythm and a slower sinus rhythm co-exist) (Schott, 1937) were observed in this case: The R-R intervals produced by conducted beats were shorter than the R-R intervals between two successive atrioventricular beats; the R-R interval following a conducted beat was shorter than the R-R intervals of successive atrioventricular beats if this beat too was produced by a (second) conducted beat (fig. 2) or was materially lengthened if an auricular impulse was conducted through the atrioventricular centre, there interfering with the production of the atrioventricular rhythm, but being blocked below the atrioventricular centre failed to yield a ventricular response (fig. 3). A peculiar feature of the arrhythmia on October 24 (see fig. 4) was that the onset of conducted beats was invariably preceded by an acceleration of both the auricular and atrioventricular rhythms, the P-P intervals being shortened from 27-28 to 24-25/100 seconds and the R-R intervals from 52-56 to 49-50/100 seconds. Simultaneous variations in the rate of two co-existing rhythms have been described by Scharf and Weiser (1924) and attributed to vagal influence. A diagram of a continuous record of 103 ventricular cycles, obtained on October 24, is shown in fig. 4.

Tinct. digitalis m vii , b.d. for two days and t.d.s. for another two days abolished the attack on November 1, sinus (? ectopic auricular) rhythm, regular, rate 71, ensuing. From November 3 onwards he was given tinct. digitalis m vii , b.d. and quinidine sulph. 5 grains t.d.s. on alternate days with clinical improvement and persistent regular rhythm of normal rate. Occasional coupled beats were heard on auscultation and recorded on December 4 whereupon the dose of digitalis was reduced to m v .

Repeated radiological examinations of the chest failed to show any enlargement of the left auricle, nor was a double contour on the right border found again. The right auricle was markedly enlarged. No mitral diastolic murmur was heard.

Grateful acknowledgment is made to Dr. A. H. Douthwaite, under whose care the patient was admitted to Guy's Hospital, for his kind permission to demonstrate the case again and publish his notes.

Dr. A. Elkeles agrees that this is not a case of mitral stenosis. The enlargement of the right heart, which seems to be mainly caused by dilatation of the right auricle, is, however, difficult to explain. The radiograms of the chest taken in the posterior-anterior and particularly in the right oblique position with an opaque oesophagus demonstrate the enlargement of the right auricle by showing a definite bulge of the terminal part of the oesophagus, but no displacement of the lower third of the oesophagus is present, which excludes dilatation of the left auricle. Since isolated enlargement of the right auricle is so far unknown in organic heart disease it may be suggested that in this particular case of severe and long-continued paroxysmal auricular tachycardia with A-V block the auricles are subjected to the main strain, and incomplete emptying of the right auricle may give rise to increased intra-auricular pressure with consequent dilatation. Recent observations by Campbell, Currie, Hunter and Evans have shown that even after single attacks of paroxysmal auricular tachycardia without A-V block inversion of T waves were present in the E.C.G., which although of a temporary character may remain for some months. These authors explain the temporary inversion of T waves as a result of extra strain on the heart muscle during the attacks. It may be of interest to investigate whether isolated enlargement of the right auricle may be a feature in paroxysmal auricular tachycardia with A-V block.

valuable monograph on leukaemia by Forkner (1938) the conclusions of the various authors quoted by him seem unfortunately rather unhesitatingly accepted. An excellent account of the condition was given by Sequeira and Panton (1925) (quoted by Whittle and Hughes-Jones, 1943) who proposed the term lymphoblastic erythrodermia. In the older dermatological literature, Hebra's term of pityriasis rubra was probably used in too wide a sense, including also cases showing little, if any, pityriasis. In this condition, if I understand the term correctly, one finds thinning of the skin rather than stiffness connected with thickening. The term "lipo-melanin reticulosis", used in Dr. Robb-Smith's report, was coined by Pautrier and Woringer (1937) but they proposed it as a rather generic term describing the presence of melanin and some lipid substance in abnormally increased amounts in the lymph nodes in many forms of erythrodermia, including those secondary to eczema, psoriasis, pemphigus, arsenic poisoning, &c., and they thought that the accumulation of these substances in the lymph nodes is due to a disturbance of their exchange between skin and epidermis.

Regarding any form of systemic treatment, the literature is silent and in Fraser's case (1943) the eventual improvement was not attributed by the author to a previous course of X-ray treatment.

Splenomegaly with Leucopenia.—A. L. WINGFIELD, M.D.

M. A., aged 28. Indian Scaman. Admitted 13.9.45 with sore throat, pain in the neck and pain in abdomen. Mild jaundice was present but soon disappeared.

On examination.—Looked ill. Temperature 100.4. P. 90. R. 20. Follicular tonsillitis on left side with enlarged and tender cervical glands. Heart and lungs normal. B.P. 100/60. Liver enlarged two fingers, spleen enlarged to level of umbilicus. Notch easily felt. Throat swab no K.L.B. Blood films for malaria negative.

6.10.45: Hb. 40%. W.B.C. 1,800 per c.mm. Van den Bergh—indirect positive. Fouchet's test—strong positive. Splenic and sternal punctures negative for Leishman-Donovan bodies and malaria parasites. Formol-gel and urea-stibamine tests negative.

Faeces: One *Ascaris lumbricoides* found, subsequently no ova or cysts. Temperature persisted at about 101° and in view of the granulocytopenia treatment was started with Pentide and Plexan. The temperature gradually settled and was normal from October 2 to 7.

R.B.C. 1,430,000 per c.mm. Hb. 35%. W.B.C. 3,300 per c.mm. Polymorphs 40%. No anisocytosis or poikilocytosis.

A spike of temperature on 7.10.45 led to antimalarial treatment and the temperature again settled and remained normal until 24.11.45.

Recent investigations.—Widal reaction negative for typhoid and *abortus* organisms. W.R. negative.

Blood-count (28.11.45).—R.B.C. 2,800,000 per c.mm.; Hb. 63%; W.B.C. 2,600 per c.mm. Differential white: Polys. 42%, small lymphos. 50%, large monos. 4%, large lymphos. 2%, eosinos. 2%. No malaria parasites seen.

In view of the recurrence of fever neostibosan is now being given. Splenic enlargement unchanged but recently abdominal distension. There is now very little fever.

Kala-azar is the obvious diagnosis but all tests for this are negative.

Dr. Herbert Levy said that had this syndrome been found in a European he would have first thought of Hodgkin's disease. Pernicious anaemia seemed another possibility; part of the splenic enlargement might in this case be due to previous malaria.

Paroxysmal Auricular Tachycardia with Auriculo-Ventricular Block; Follow Up; Transient Dissociation with Interference.—A. SCHOTT, M.D.

Male, aged 42. Previously demonstrated on February 9, 1945.

In October 1944 he caught a "heavy cold" and five days afterwards had a sudden attack of very marked shortness of breath with a choking sensation, substernal pain and tachycardia and collapsed. He was first admitted to Guy's Hospital on December 1, 1944, where a diagnosis of paroxysmal auricular tachycardia with auriculo-ventricular block was made. For further details see Schott, 1945.

He was discharged on July 18, 1945, with regular rhythm and normal rate and was put on a maintenance dose of quinidine sulph. 3 grains b.d. He felt well until September 1945 when tachycardia recurred and he was readmitted to Guy's Hospital on September 9, 1945; paroxysmal auricular tachycardia with 2:1 block again was found. Alternation in cycle length of the P-P intervals was marked (see fig. 1) (Barker, Johnston and Wilson, 1943). Tinct. digitalis m xv, q.i.d. given during two and a half days, abolished the attack and on September 28, 1945, a ventricular rate of 65 with regular rhythm was recorded. A maintenance dose of tinct. digitalis m vii once daily produced coupling owing to ventricular extrasystoles. With quinidine sulph. 3 grains six times a day, started on October 10, regular rhythm (rate 60-70) persisted until October 21 when both ventricular and pulse-rates rose to about 128. Electrocardiograms (October 22, 23 and 24) showed recurrence of paroxysmal auricular tachycardia; the ventricular rhythm being a little faster than *half* the auricular rate there was occasional interference with the ventricular rhythm by conducted auricular beats; dissociation with interference. Most of the features known to occur in the ordinary form of dissociation with interference (in which a faster atrioventricular rhythm and a slower sinus rhythm co-exist) (Schott, 1937) were observed in this case: The R-R intervals produced by conducted beats were shorter than the R-R intervals between two successive atrioventricular beats; the R-R interval following a conducted beat was shorter than the R-R intervals of successive atrioventricular beats if this beat too was produced by a (second) conducted beat (fig. 2) or was materially lengthened if an auricular impulse was conducted through the atrioventricular centre, there interfering with the production of the atrioventricular rhythm, but being blocked below the atrioventricular centre failed to yield a ventricular response (fig. 3). A peculiar feature of the arrhythmia on October 24 (see fig. 4) was that the onset of conducted beats was invariably preceded by an acceleration of both the auricular and atrioventricular rhythms, the P-P intervals being shortened from 27-28 to 24-25/100 seconds and the R-R intervals from 52-56 to 49-50/100 seconds. Simultaneous variations in the rate of two co-existing rhythms have been described by Scharf and Weiser (1924) and attributed to vagal influence. A diagram of a continuous record of 103 ventricular cycles, obtained on October 24, is shown in fig. 4.

Tinct. digitalis m vii, b.d. for two days and t.d.s. for another two days abolished the attack on November 1, sinus (? ectopic auricular) rhythm, regular, rate 71, ensuing. From November 3 onwards he was given tinct. digitalis m vii, b.d. and quinidine sulph. 5 grains t.d.s. on alternate days with clinical improvement and persistent regular rhythm of normal rate. Occasional coupled beats were heard on auscultation and recorded on December 4 whereupon the dose of digitalis was reduced to m v.

Repeated radiological examinations of the chest failed to show any enlargement of the left auricle, nor was a double contour on the right border found again. The right auricle was markedly enlarged. No mitral diastolic murmur was heard.

Grateful acknowledgment is made to Dr. A. H. Douthwaite, under whose care the patient was admitted to Guy's Hospital, for his kind permission to demonstrate the case again and publish his notes.

Dr. A. Elkeles agrees that this is not a case of mitral stenosis. The enlargement of the right heart, which seems to be mainly caused by dilatation of the right auricle, is, however, difficult to explain. The radiograms of the chest taken in the posterior-anterior and particularly in the right oblique position with an opaque œsophagus demonstrate the enlargement of the right auricle by showing a definite bulge of the terminal part of the œsophagus, but no displacement of the lower third of the œsophagus is present, which excludes dilatation of the left auricle. Since isolated enlargement of the right auricle is so far unknown in organic heart disease it may be suggested that in this particular case of severe and long-continued paroxysmal auricular tachycardia with A-V block the auricles are subjected to the main strain, and incomplete emptying of the right auricle may give rise to increased intra-auricular pressure with consequent dilatation. Recent observations by Campbell, Currie, Hunter and Evans have shown that even after single attacks of paroxysmal auricular tachycardia without A-V block inversion of T waves were present in the E.C.G., which although of a temporary character may remain for some months. These authors explain the temporary inversion of T waves as a result of extra strain on the heart muscle during the attacks. It may be of interest to investigate whether isolated enlargement of the right auricle may be a feature in paroxysmal auricular tachycardia with A-V block.

Para-oesophageal Hernia as a Cause of Recurrent Gastro-intestinal Hæmorrhage.—

A. ELKELES, M.D.

Mrs. R. L., aged 75. February 1943: Complained of general weakness, restlessness and empty feeling in the head. A few days previous to examination urgent and frequent desire to open bowels was felt and tarry stools were observed. These symptoms have recurred in varying intervals for the last twenty-five years (approximately once or twice yearly). During these attacks patient is confined to bed for a week or two.

On examination.—Patient very pale but well nourished. Lungs, heart and blood-pressure normal. Abdomen: No palpable tumour. Blood: Marked secondary anaemia. Urine: Albumin, sugar negative. Faeces: occult blood strongly positive.

Radiological examination: Round translucent shadow, the size of a large orange behind the heart (fig. 1). Barium meal revealed this shadow to be caused by protrusion of the proximal part of the stomach into the posterior left mediastinum. Œsophagus shows a diverticulum in its middle third (fig. 2). In the Trendelenburg position (right oblique) the lower third of the Œsophagus is elevated above the diaphragm and lies beside the herniated part of the stomach. The Œsophagus is of normal length (fig. 3). No evidence of peptic pathology or neoplasm in the gastro-intestinal tract, no polyposis of large intestine detected.

Course.—Satisfactory recovery and restoration of blood picture to normal on iron medication.

Re-examination (November 1945).—X-ray findings of Œsophagus and stomach unchanged. Only one attack of melæna since February 1943. Now symptom-free.

Comment.—Recently another case of para-oesophageal hernia in a male aged 70 was observed by me. Severe secondary anaemia was the only clinical sign. Diet and iron medication brought about a quick recovery. These cases and evidence from the literature indicate that gastro-intestinal hæmorrhage or severe anaemia may sometimes be the only clinical signs in para-oesophageal hernia. This condition should therefore be included in the differential diagnosis of pathological processes responsible for gastro-intestinal bleeding in advancing years. Hæmorrhage in these cases may be caused by congestion of the mucosa, by small erosions or even ulceration of the protruded stomach, changes which can be visualized by gastroscopic examination. Surgical intervention in para-oesophageal hernia, even when associated with gastro-intestinal bleeding, is not always necessary, and should only be resorted to if incarceration of the stomach in the Œsophageal hiatus with symptoms of obstruction occur or when medical treatment fails to control recurrent hæmorrhages.

FIG. 1.—Postero-anterior position: proximal half of stomach lies behind the heart.

FIG. 2.—Right oblique position: diverticulum of middle third of œsophagus is seen above the apex of the protruded stomach.

FIG. 3.—Trendelenburg position—right oblique; the parallel mucosal folds of the œsophagus can be seen through the gas-bubble of the protruded part of the stomach.

presenting this syndrome. There are records in the literature of 4 more cases, one recorded by Loeper, Lemaine and Patel—they suggested that the Chauffard-Still syndrome might be looked upon as one of the reticulo-endothelioses with the spleen as the essential site of the disease.

The rationale of this treatment is not known, but the clinical results have been encouraging and some patients have now been followed up for seven years.

In my opinion rheumatoid arthritis is a psychosomatic syndrome in which metabolic and psychological factors appear to play a more important role than does focal infection. There are certain points of interest which may give a possible clue as to the reason for the clinical improvement: In (1) starvation, (2) pregnancy (4th to 8th month), (3) jaundice (incidental, infective, or obstructive), it is the experience of clinicians that there is often a dramatic diminution in the severity of the symptoms of rheumatoid arthritis. This improvement, however, is of short duration. In all these conditions there is a retention of cholesterol in the blood. After splenectomy for acholuric jaundice the blood cholesterol is said to rise. Cholesterol is said by Herman Zondek to be the mother-substance of hormones, vitamins and carcinogenous substances. From the oxidation of certain side-chains of the cholesterol formula are derived: (a) the nucleus of bile salts, (b) testosterone, (c) steroids of the adrenal cortex, (d) stilboestrol: all substances which are used by clinicians in the treatment of rheumatoid arthritis.

[February 8, 1946]

Chronic Haemolytic Polycythæmia.—LEO RAU, M.D., M.R.C.P., R. J. V. PULVERTAFT, M.D., F.R.C.P., and J. G. HUMBLE, M.R.C.S., L.R.C.P.

Mrs. D., aged 37, was first seen by one of us (L. R.) in November 1945 complaining of general fatigue, dyspnœa, ulcers of her legs and peculiar blue spots on her nose, cheeks and both legs.

Good health until 1940 but in that year noticed the development of brown spots on her right leg. These spots developed into an ulcer. In 1943 she again started an ulcer of the right leg. Then she noticed some discoloration of her face, ever since she had the symptoms described above.

She has one boy aged 9; at the time of the pregnancy there were no complications, but she had a severe post-partum hæmorrhage. Further, she had severe hæmorrhage after the extraction of some teeth.

Family history.—Her mother has suffered from pernicious anæmia since 1942, and her blood-count is now normal. Mrs. D. is one of nine children, one of her sisters had a hysterectomy for fibroids and another, who is now 29, had a goitre removed.

On examination.—Well covered, very marked cyanosis of nose, chin and cheeks. No jaundice, or œdema. No glands palpable, but the spleen is enormously enlarged, filling almost two-thirds of the abdomen. The liver is easily palpable. The fundi are normal. In November 1945 there were several small ulcers of the lower thirds of both legs. Still more striking were venectasie of the stellate type with centripetal flow. B.P. 135/85. P. 66-72.

Investigations.—Blood-count: R.B.C. 6,530,000 per c.mm.; Hb. 140%; W.B.C. 9,200 per c.mm. Polys. 60%, lymphos. 30%, monos. 4%, eosinos. 4% and basos. 2%. One normoblast was found and there was marked poikilocytosis, anisocytosis and spherocytosis. Platelet count of 95,000 per c.mm. Serum bilirubin 1.6 mg.%. (Indirect.)

X-ray of skull and gall-bladder normal. X-ray of abdomen showed an enormous spleen.

The diagnosis of chronic hæmolytic polycythæmia was made.

Further investigations.—Reticulocyte count 3%. Fragility of R.B.C.'s from 0.3% to 0.55% NaCl.

Lastly her father, mother, two sisters and three brothers were examined, and all the blood films and reticulocyte counts were normal.

Comment.—The outstanding features of her case are polycythæmia, splenomegaly, and ulcers and venectasie of the legs. Clinically ulcers of the legs as in Mrs. D. occur only in acholuric jaundice and in sickle-celled anæmia. The investigations carried out in this case clearly demonstrate the presence of all the characteristics of acholuric jaundice. Usually patients with this disease have hæmolytic anæmia, but Mrs. D. produced polycythæmia as a sign of hypercompensation of her bone-marrow.

Splenectomy in the Treatment of the Rheumatoid Type of Arthritis.—FRANCIS BACH, D.M.

J. G., an unmarried girl aged 22, a clerk, was admitted under my care to the Rheumatic Unit at St. Stephen's Hospital on 10.7.45, suffering from the rheumatoid type of arthritis in an advanced and active phase.

Past history.—She is a shy, retiring girl, the youngest child of elderly parents. Three years ago she was seen by me at Out-patients, with a swelling of one finger. Diagnosis of rheumatoid arthritis was made. Treatment was instituted, but within a year she had marked swelling of the elbows, wrists, hands, knees, and ankles. Her condition progressed and she was admitted to hospital. Prior to admission she had lost weight, she felt ill, and had no appetite.

She was a tense, worried, underweight girl, with marked poor posture, marked deformity of the hands with wasting of the interossei muscles, slight ulnar deviation, limitation of dorsiflexion of the wrists, muscle spasm and limitation of elbow extension, slight limitation of hip movement, effusion in both knees with limitation of knee flexion, swelling of the ankles with limitation of dorsiflexion, deformity of the toes, limitation of shoulder movement. Epitrochlear, cervical, and inguinal glands were enlarged. The spleen was not palpable. There was a post-pharyngeal hyperplasia.

Family history.—Mother diabetic, nothing else of immediate interest.

Special investigations on admission.—Temperature normal, blood sedimentation 40 mm. Westergren at end of first hour. Blood-count: R.B.C. 5,000,000; Hb. 106%; W.B.C. 7,300. Polys. 67%, lymphos. 22%, monos. 9%, eosinos. 2%, basos. 0. Urine analysis normal. Throat swab no K.L.B. or hæmolytic strept. X-ray slight opacity of the antrum. Hands early rheumatoid type of change with diminution of joint space in proximal interpharyngeal joints; chest catarrhal signs. Wassermann and Kahn negative; blood urea 35 mg. per 100 ml., uric acid 2.7 mg. per 100 ml., van den Bergh direct action negative, indirect action less than 0.5 units bilirubin. Takata-Ara reaction suspicious. Thymol turbidity tests 5 units. Blood-sugar curve: Before sugar 70, subsequently 83, 88, 100, 76 mg. for 100 ml. Urine no sugar. Fæces: undigested muscle fibres, no starch detected. Total fat 23.8% of dried fæces, neutral fat 6.3%, free fatty acid 3.7%, combined fatty acid 13.8%, split fat 17.5%, unsplit fat 6.3%. Blood platelets 180,000 per c.mm., bleeding time normal. C.D.T. anti-complementary.

Psychological report: Highly strung nervous type. Reactions are purely those of the anxiety type with a good appreciation of her own difficulties. No evidence of any tendency to seek escape in somatic disability, and no evidence of hysterical temperament. I do not feel that there is a psychogenic factor in her condition (Dr. Dalziel).

Treatment included rest, full diet, extra vitamins, amytal $\frac{3}{4}$ grain q.i.d., prostigmine 15 mg. t.d.s. for one week, insulin 10 units t.d.s., a.c.; physiotherapy in the form of relaxation exercises; splints to hands, knees, and feet; heat and painless movements, breathing and postural exercises on slings, short wave galvanism, faradism to quadriceps muscles, &c. She failed to improve.

At my suggestion Mr. Waters performed splenectomy on her on 6.11.45. There was immediate improvement in her general health, with marked reduction of muscle spasm and joint swelling. The post-operative period was uneventful. She continued with her physical treatment, and within a fortnight was able to walk about the ward with little discomfort or disability. She is now back at work as a clerk.

Immediately before operation the blood platelet count was 392,000. After operation this increased to 480,000. The blood cholesterol was 160 mg. per 100 ml.

This patient is shown to demonstrate the possible value of splenectomy in the treatment of rheumatoid arthritis. She is one of a series of 8 patients under my care who have been carefully selected, and have failed to respond to the known, recognized methods of treatment.

The purpose of the operation is to reduce pain and muscle spasm, and, when present, pyrexia, and to try to prevent the further progress of crippling.

In 1940 with Oswald Savage I published in the *Annals of the Rheumatic Diseases* the detailed reports of three of my patients on whom splenectomy had been performed. Since then in 5 more patients this operation has been performed at my instigation.

In 1930 Paul Chevallier emphasized the similarity of the Chauffard-Still syndrome to the arthritic manifestations of Hanot's "biliary cirrhosis", described the ineffectiveness of the various kinds of treatment, and noted that in no instance had the spleen been removed. In 1932 Hanrahan and Miller reported the result of a splenectomy on a patient

Operation.—On opening the abdomen a large quantity of blood-stained peritoneal effusion escaped. Roughly half-way down the small intestine was a blackened, obviously gangrenous loop of gut, adjoining which was a thick oedematous hard mesenteric mass. A length of gut three feet in length, with as deep a wedge of mesentery as was deemed advisable, was then resected, the line of section being made about 6 in. away from any doubtfully coloured intestine at each end. As the mesentery was cut it was clear that the thrombosis had extended beyond the line of section as clot was extruded from the cut veins.

An end-to-end anastomosis was performed and the gap in the mesentery closed, but in view of the presence of thrombosed veins in the cut edge, it was decided to make an entero-anastomosis between loops above and below the junction to act as a safety valve in case of further infarction.

After operation he was given an intravenous drip of normal saline to which heparin in proportion of 7,500 units to each pint was added. The following morning his condition was quite good, his temperature 99° and his pulse-rate 100.

The heparin was continued in the intravenous drip and was increased to 15,000 units per pint on the second day. On the eighth day a slight oozing of fresh blood from the centre of the abdominal wound appeared and it was thought advisable to stop giving heparin. The bleeding stopped the following day and his convalescence was thereafter uneventful.

The course of intramuscular injections of penicillin, 120,000 units daily, was continued until the twelfth day. His bowels acted with the aid of an olive-oil enema on the third day after operation and thereafter remained regular. He has now resumed his duties and is in normal health.

Suppurative Pylephlebitis with Recovery.—F. D'ABREU, Ch.M., F.R.C.S.

E. C., aged 26, a gunner in the R.A., was admitted on August 21, 1945, to Westminster Hospital (G 7359). His previous history was that in January 1945 he had been admitted to another hospital with an appendix abscess. On February 1 he had an appendicectomy performed with drainage.

On February 15, 1945, he had a left subphrenic abscess drained and a month later developed a left empyema which was successfully treated by aspiration and penicillin replacement.

He was complaining of pain in the upper abdomen with frequent rigors. His temperature was 103° and his pulse 140.

On examination of his abdomen there was an incisional hernia in the R.I.F., which was red and tender. There was more marked tenderness on the right side over the liver area but no rigidity or evidence of general peritonitis. An X-ray showed raising of the diaphragm on both sides with small areas of collapse at the base of both lungs. A diagnosis of right subphrenic abscess was made and on August 22, 1945, a right subcostal incision was made posteriorly after an aspiratory needle had withdrawn pus. On incising the diaphragm no pus was found in the subphrenic space. The peritoneal cavity was discovered to be shut off below by adhesions. A needle was then inserted in the same line as the diagnostic aspiration and pus was found in the liver. An incision was made into an abscess cavity about the size of an orange in the liver substance and some creamy, odourless pus sucked out. A rubber drainage tube was placed into the abscess cavity and the wound closed firmly around this.

Penicillin was given intramuscularly 120,000 units per day and into the tube twice daily, the tube being clipped off after each administration for one hour.

Culture of the pus showed a micro-aerophilic streptococcus, non-hæmolytic and penicillin-sensitive.

Thirteen days after operation his temperature became normal and penicillin was stopped on the sixteenth day.

A week later fever and rigors again set in and a further course of penicillin was given which reduced the temperature after seven days but was continued for twenty days with a daily dosage of 180,000 units.

On October 15, high fever and rigor recommenced, and on October 18 the liver was needled but no pus was found. A third course of penicillin at the same dosage of 180,000 units daily was given by intramuscular drip for seventeen days but the temperature was not affected and on November 10 it was decided to explore the liver by laparotomy. An enormously enlarged liver was found with a hard mass high up in the right lobe. This was explored and a little pus withdrawn from a deep puncture. The mass was considered to be an inflammatory hepatitis and the liver was not incised. A drain was left down to this part of the liver through a stab wound directly over it and another left in the abdominal wound which was then closed. Penicillin was again given by intramuscular drip and after a week pus began to discharge freely through the stab wound and the

P.S.—Since the Clinical Meeting took place, a sternal puncture was performed. This is the result:

					%
Myeloblasts	1	0.3
Premyelocytes	7	2.3
Neutrophil myelocytes	40	13.3
Eosinophil myelocytes	3	1.0
Neutrophil polymorphs	40	13.3
Eosinophil polymorphs	2	0.6

Orthochromic normoblasts	28	9.3
Plasma cells	1	0.3
Myeloid erythroblast ratio	1	3.1

The striking feature of this marrow is the very large number of nucleated red cells many of which (5.6% of the total cell count) are in mitosis.

Hæmopoiesis is, however, *normoblastic*.

This seems to be the marrow of a patient responding to increased destruction of red cells.

Therefore, the patient is essentially suffering from a *hæmolytic process*.

Resection of Small Intestine for Mesenteric Venous Thrombosis.—F. D'ABREU, Ch.M., F.R.C.S.

Cases of recovery after resection of the intestine for mesenteric vascular occlusion are rare and are nearly all in arterial embolic cases. Recovery after operation for mesenteric venous thrombosis is extremely uncommon as the trauma consequent to resection, however slight, is likely to produce a further spread of the thrombotic process centrally.

The successful outcome in this case is ascribed to four precautions which were taken to guard against the risk of further infarction: (1) A wide excision was performed with removal of a deep wedge of mesentery. (2) After end-to-end anastomosis of the cut ends, a lateral anastomosis between portions of gut respectively a foot above and below the junction was made to act as a safety valve in the event of thrombosis at the site of the repaired mesenteric gap. (3) Heparin was given intravenously for eight days. (4) Penicillin was administered empirically to deal with any systemic infection causing the thrombophlebitis.

Case Record, Westminster Hospital (G8256).—A Staff Sergeant, age 40, in the Belgian Army, was admitted on September 18, 1945, complaining of a dull heavy pain just below the xiphisternum. This had started suddenly on the morning of September 11, and he had been kept in bed at a Casualty Reception Station. The pain got less but still persisted and he was sent up to Westminster Hospital a week later.

His previous history was of a thrombophlebitis in the left internal saphenous vein just above the knee, after a bruise in that region in October 1944. Whilst in bed with this, he had a severe massive collapse of the right lung from a pulmonary embolus, followed a week later by thrombosis of the right internal saphenous in the thigh. Examination revealed tenderness and resistance in the epigastrium but the rest of the abdomen was normal. No mass could be felt and the abdominal wall moved on respiration. His temperature was 101° and his pulse 80. Blood-pressure 130/80; heart sounds normal. He was obviously in great discomfort, but no definite diagnosis could be made and it was decided to keep him under observation, as a possible subacute pancreatitis or high retro-cæcal abscess.

A white cell count totalled 14,800 per c.mm. His bowels had been constipated before admission but an enema the following morning produced a good result. Gregerson's test of the stool for occult blood was negative. The result of a further enema on the 22nd was also apparently normal. His temperature gradually fell during the next five days, at the end of which it was normal and his pulse 70.

His epigastric resistance had gone but he still complained of epigastric pain and tenderness. On the evening of September 24, the seventh day after admission, he complained that the pain in his abdomen was much worse and his chart showed a gradually rising pulse and a temperature of 99° F. He had vomited and an enema had produced only a small constipated stool of normal colour.

On examination he was resistant and tender all over the abdomen, which was moderately distended. On auscultation no intestinal movements could be heard. A diagnosis of an acute small intestinal obstruction was made and the patient taken to the theatre.

History (9.10.42).—Torpedoed off W. Coast of Africa, subsequently spending two hours in water and ten days in lifeboat. Apparently satisfactory recovery. One month later attack of conjunctivitis, duration one month.

About February 1943 onset of general fatigue and lassitude, followed a few weeks later by aching pains in limbs and back. Symptoms were intermittent, and he remained at work. Started to lose weight about December 1944.

March 1945: Sudden attack of stiffness involving whole body except head and neck. Admitted to hospital and treated as fibrositis without-improvement.

19.10.45: Admitted Archway L.C.C. Hospital. Diagnosis: "Myositis of unknown origin." Eosinophilia suggested trichinosis. X-rays of limbs showed no opacities. No muscle biopsy. Treated with physiotherapy. Condition slowly deteriorated. Soon after admission complained of dimness of vision, followed a few weeks later by thirst and polyuria. Discharged 22.12.45 and admitted to Seaman's Hospital 27.12.45.

Positive findings.—Apathy and profound lassitude. General wasting. Dry, sore tongue. B.P. 190/130. Bilateral diminution of visual acuity, retinal hæmorrhages and exudate. Muscular wasting, poor tone; movement and co-ordination normal. Sensation: Small area of diminished light touch on dorsum of both feet. Absent tendon reflexes. Abdominal reflexes present. Plantars flexor. Heart not enlarged.

Investigations 31.12.45.—X-ray of chest, right leg, skull, nothing abnormal found.

31.12.45: R.B.C. 5,190,000; Hb. 102%; W.B.C. 23,000. Polys. 87%, small lymphos. 11%, large lymphos. 1%, eosinos. 1%. W.R. and Kahn negative. Serum calcium 9.76 mg. %.

1.1.46: Blood urea 47.2 mg. %.

4.1.46: Fæces—no cysts or ova seen.

14.1.46: Blood sugar at 10.15 a.m. 0.156% (not fasting).

Urine: This has been examined daily, and shows a high output of between 200 and 250 oz. of low sp.gr. (av. 1004.5). The output is constantly in excess of the intake. Traces of sugar and scanty hyaline tube casts have been found on two occasions. There are sometimes traces of albumin. Reaction consistently alkaline.

Blood urea 29 mg. per 100 c.c. B.S.R. 11/200 in 1 hour.

Progress.—Following admission condition unchanged. Thirst, polyuria and dimness of vision have been chief symptoms. Backache severe initially but absent recently.

Exhibition of pitressin $\frac{1}{2}$ c.c. b.d. had no therapeutic effect. Restriction of the fluid intake resulted in no greater concentration of urine.

1.2.46: Re-examination showed a faint response of biceps, triceps and supinator jerks on both sides. Faint response both knee-jerks. Ankle-jerks still absent. B.P. 160/130.

Comment.—This patient showed most of the features of periarteritis nodosa but there were no skin nodules. Hypertension without radiological evidence of cardiac enlargement is remarkable. Leucocytosis and fever suggest an infective process. The diagnosis of cysticercosis was also suggested.

POSTSCRIPT.—This patient died on March 1 and autopsy showed hypertrophy of the left ventricle with renal changes characteristic of malignant hypertension.

Chronic Myeloid Leukæmia with a Goitre and Raised B.M.R.—J. S. RICHARDSON, M.V.O., M.D., M.R.C.P.

Ellen M., aged 54, a housewife, was admitted to St. Thomas's Hospital under the care of Professor O. L. V. de Wesselow on 7.11.45.

A swelling in her neck was first noticed about one year before, and a month or so later she noticed that she was short of breath on exertion, and began to experience attacks of palpitations, with a feeling at night as if her heart was beating irregularly. She has never had any anginal or precordial pain and her ankles had not been noticed to swell.

She found that she was getting extremely emotional and nervous at that time and while she was not upset by such warm weather as we had in the summer, she had felt the cold less than usual during the winter months. Her normal weight was 7 st. 5 lb. but she had noticed she had been getting much thinner during the last five months and at the same time she was increasingly tired, and life was more and more of an effort. She had had no dyspepsia and no abdominal pain, but her appetite was very poor. In the past she had had no serious illnesses but she had always been rather nervous.

On examination.—She was extremely thin with a moist skin and bright eyes. There was no tremor of her hands. Weight 5 st. 5 lb. An adenoma of the right lobe of the thyroid gland was present with some diffuse enlargement. Pulse-rate 120. B.P. 180/100. No abnormal physical signs were found in the heart.

Lymph nodes: A few small glands were felt in the neck on the right side and in the left axilla.

abdominal incision. The temperature gradually settled and the penicillin was stopped. The pus again grew the same micro-aerophilic streptococcus.

On November 24 he became tender over the left lobe of the liver after the discharge of pus had ceased and his temperature again rose. On December 3 his abdominal wound again discharged pus and the left-sided tenderness subsided as did his fever.

On December 12 his temperature and pulse again rose and he again complained of pain in the area of the right side of his liver and a resection of a portion of the tenth rib in the post-axillary line was performed. This time a subphrenic abscess was found. For four days before operation and for eight days afterwards he received 400,000 units of penicillin daily by intramuscular drip and 50,000 daily into a tube draining the subphrenic abscess. After this operation and course of penicillin, his temperature and pulse returned to normal and have remained so ever since. He is now ambulatory and in good health.

This patient had two separate large hepatic abscesses in the right lobe seen at operation and almost certainly another large one in the left lobe.

On the advice of Dr. T. L. Hilliard, who gave me valuable help in treating this patient, a course of methionine was given almost throughout his long illness to counteract a probable depression of liver function. This was tested by Dr. N. F. MacLagan on December 7 towards the end of his illness and gave normal results.

This case shows that it is always worth while exploring the abdomen in a case of suppurative pylephlebitis and might show reason for giving greatly increased penicillin dosages where penicillin-sensitive organisms are not easily accessible to the systemic blood supply.

Cesophagectomy for Carcinoma. Restoration of Function by an Ante-thoracic Jejunal Graft.—VERNON C. THOMPSON, F.R.C.S.

E. W. B., male, aged 70. Admitted to hospital 14.5.45.

History.—Six months' increasing dysphagia with retrosternal pain on swallowing.

On examination.—Fairly fit man; chronic bronchitis. B.P. 170/100. Able to swallow semi-solids. Barium swallow showed obstruction at middle third of oesophagus; and a right-sided aorta. Cesophagoscopy: An ulcerated growth 30 cm. from the gums. Biopsy: squamous-celled carcinoma.

19.6.45: *Operation (1).*—A length of jejunum was mobilized according to the technique of Yudin and brought up under the skin to the level of the 2nd rib.

26.8.45: *Operation (2) Cesophagectomy.*—Through a right transpleural approach the oesophagus was removed, the upper end was brought out in the neck and anastomosed to the upper end of the jejunal graft.

Progress.—The end of the oesophageal stump sloughed and the anastomosis broke down; the patient was fed by a drip into the jejunal graft until the ends of oesophagus and jejunum were healthy. The fistula was later closed by a secondary operation. (Fig. 1.)

FIG. 1.—E.W.B. Showing ante-thoracic oesophagus made from a jejunal transplant.

Malignant Hypertension.—A. L. WINGFIELD, M.D.

A. M., ship's storekeeper, aged 30. Admitted 27.12.45. Complained of general lassitude, stiffness and aching in limbs, loss of weight, thirst, polyuria, and dimness of vision. Family and previous history non-contributory.

sensitive method they possess of assessing the degree of activity in these cases and their response to treatment (Uhlmann and Goldner, 1944; Krantz and Riddle, 1928).

The B.M.R. in our case was still +28% when the white count had fallen to 13,500 and there were no primitive cells. This might mean that the leukæmia was still active or that she had a coexisting hyperthyroidism.

It is worthy of note in this connexion that there was a large creatinuria and practically no arteriovenous blood sugar difference after an insulin-glucose test, both features of thyrotoxicosis (Griffiths, 1939). The blood iodine and cholesterol are variable in leukæmia (Turner *et al.*, 1940), and were not done. The problem was solved, however, by a further fall in the B.M.R. to +15% with a white cell count of 4,400 cells, 72% polymorphs and no primitive cells.

Idiopathic Pulmonary Hypertension.—RICHARD F. JARRETT, M.R.C.P. (for MAURICE NELLEN, M.R.C.P., M.R.C.P.Ed.).

Mary O'M., aged 26. This patient was in Hammersmith Hospital from 1.5.45 to 17.5.45 with condition as follows:

History.—One year ago she began to be breathless on exertion and now is breathless after walking quickly on the level. She had never before been breathless on exertion.

Previous history.—Healthy. No rheumatic fever. Normal child life. Two normal pregnancies with healthy children now aged 5 and 2.

Family history.—Healthy.

On examination.—Jugular venous pressure +2.3 cm. Heart: Apex beat $4\frac{1}{2}$ in. in 4th space. Systolic murmur all areas. No thrill. Heaving impulse in 3rd left space 2 in. from midline. P_2 loud. B.P. 114/82.

Investigations.—(1) X-ray: Heart much enlarged. L.V. and R.V. enlarged. Diam. $6\frac{3}{4}$ in. (6 ft. film). (2) Decholin time 12 secs. single end point. (3) E.C.G. marked right preponderance.

Progress.—Much improved by two weeks' rest in bed. She then went home but was unable to do housework because of dyspnoea. In December 1945 first noticed ankles swelling and late December 1945 first noticed neck swelling. At this time fainted twice, once on running upstairs and once after a very hot bath. No cough or hæmoptysis.

Readmitted 9.1.46.

On examination.—Normally developed young woman; moderate cyanosis lips and cheeks; slight icteric-tinged skin; orthopnoea, and dyspnoea on level walking. Oedema of ankles (disappearing with bed rest). Liver enlarged $1\frac{1}{2}$ in. below costal margin, firm and tender. Ascites. Jugular venous pressure +6 cm. Lungs and C.N.S.: normal. No clubbing of fingers. Pulse regular, 80. Heart: A.B. 5 in. in 5th space. Right border $\frac{1}{2}$ in. to right of right sternal margin. Heaving impulse to left of sternum in spaces 2, 3, and 4, max in 3. M_1 loud and sharp. P_2 very loud. A_2 normal. Systolic murmur in spaces 3 to 5 to left of sternum, max. in space 5, not conducted to axilla. No diastolic murmurs. B.P. 110/80.

Investigations.—W.R. and Kahn: negative. Blood-count: R.B.C. 5,500,000; Hb. 114%. Plasma bilirubin 2.3 mg.%. E.C.G.: Right preponderance ++ ($P_2 \uparrow T_2 T_3 \downarrow$). X-ray heart shows slight increase in transverse diameter (now $7\frac{1}{2}$ in.) compared with May 1945. Pulmonary artery more prominent. Ba. swallow: No left auricular enlargement.

Circulatory studies (Dr. Sharpey-Schafer).—Cardiac catheterization showed very greatly raised right auricular and right ventricular pressures and no evidence of left to right or right to left shunt. The arterial oxygen saturation was only slightly reduced. The resting output was moderately reduced.

Treatment.—Bed rest. Pulv. digitalis fol. 1 grain b.d. Mersalyl 2 c.c. twice weekly.

Course.—Slow symptomatic improvement during the past month in hospital.

Differential diagnosis from other causes of right ventricular hypertrophy with right heart failure, which can be excluded as follows:

(A) *Cor pulmonale.*—No clinical or radiological evidence of disease of the bronchi or lung parenchyma.

(B) *Mitral stenosis.*—Persistent absence of mitral diastolic murmur and normal left auricle on barium swallow.

The spleen: The spleen was very greatly enlarged and extended well below but not to the right of the umbilicus. The urine was normal.

Investigation and subsequent course:—B.M.R. +85%. Blood count: red cells 4,100,000; Hb. 62%; W.B.C. 310,000. Polys. 36%. Primitive granulocytes 55%; Transitional myelocytes 17%; Metamyelocytes 7%; Neutrophil myelocytes 31% (lymphocytes 2%). Urinary creatinine 98 mg. for 100 c.c. of urine. Urinary creatine 42 mg. for 100 cc. of urine.

Insulin-glucose test (the arterio-venous blood sugar difference: an indication of peripheral insulin resistance) showed no a-v difference and thus a very high peripheral insulin resistance. Thiouracil, 0.8 gramme daily, was given for four weeks (16.11.45 to 11.12.45) with some subjective improvement but the pulse-rate, the size of the spleen, and weight were unchanged; the B.M.R. was +87%, and the total white cell count 443,000 at the end of the treatment.

Deep X-ray therapy eight applications were then given, the last being on 21.12.45. Anterior and posterior splenic fields were irradiated and a total dosage of 500 r was given to each field. The spleen was very considerably reduced in size, at the end of this treatment, the pulse-rate had dropped to between 90 and 100, her weight was unchanged, the B.M.R. had fallen to +32% and the total white cell count was 100,000.

Polys. 58.5%. Primitive granulocytes 24.5%; transitional myelocytes 7%; metamyelocytes 3%; neutrophil myelocytes 14.5%. Urinary creatinine 1,050 mg. per 100 c.c. urine. Urinary creatine 245 mg. per 100 c.c. urine.

A second course of deep X-rays ended on January 10, 1946, and a total dosage of 200 r was given to both anterior and posterior splenic fields. Following this course the spleen was no longer palpable, the pulse-rate between 70 and 80, the B.M.R. was +32% and the total white count 20,350. Polys. 74%. Primitive granulocytes 6%. All metamyelocytes.

On January 21, 1946, the a-v difference was still minimal and the urinary creatinine 770 mg. per 100 c.c.; urinary creatine 390 mg. per 100 c.c. The B.M.R. was +28%, the leucocyte count 13,500. Polys. 85%. No primitive cells.

On 6.2.46 her B.M.R. was +15% and the leucocyte count 4,400 with 72% polymorphs and no primitive cells. Her general condition was definitely improved and her weight had risen by 3 lb.

A considerable rise in the B.M.R. is commonly found in leukaemia.

Gunderson (1921) reported 19 cases with a variation of +6% to +80% and Minot and Means (1924) found a raised B.M.R. in 72, and showed that the amount of pulse elevation for a given rise in B.M.R. was essentially the same as in hyperthyroidism. They drew attention to the marked clinical similarity between hyperthyroidism and chronic leukaemia particularly in those symptoms that are referable to increased heat production such as an increased tolerance to cold, sweating, loss of weight and dyspnoea.

Friedgood (1932) was even more impressed by the similarity between the two conditions and treated 10 cases of lymphatic leukaemia with Lugol's iodine on the supposition that the fundamental disturbance in both was a hyperactivity of the sympathetic nervous system, and that Lugol's solution acted as a sedative. He claimed a significant reduction in the B.M.R. in 6 of these 10 cases and 4 of these also showed a proportional drop in pulse-rate.

Encouraged by these views Dameshek *et al.* (1934) subjected a woman of 42 with aleukaemic leukaemia to total thyroidectomy four months after Lugol's iodine (10 minims t.d.s.) and two and a half months after deep X-ray therapy to the spleen had failed to reduce the B.M.R. or to alter appreciably the size of the spleen and lymph nodes. They reported a very large reduction in size of the spleen and lymph nodes after operation and found that the lymphoblasts disappeared entirely from the peripheral blood. The B.M.R. fell to -22% in three months and the patient was then given thyroid by mouth. The thyroid gland showed no evidence of hyperplasia and presumably played no part in raising the B.M.R.

This was to be expected as the very high oxygen requirement of the leukaemic cells is regarded as being the cause of the increased metabolism, and the number of primitive cells and the level of the B.M.R. show a direct relationship to each other in most cases (Riddle and Sturgis, 1927). There are, however, instances where this relationship does not appear to exist and a high B.M.R. may be found while the cell count in the peripheral blood is low. An explanation of this may be that the disease is still in an active phase, the blood-forming organs full of primitive cells and the blood free of them by chance. Again a high count may be found in the blood although the B.M.R. has fallen to normal as a result of deep X-ray therapy to the spleen, indicating that sufficient treatment has already been given and that the cells will fall to normal without further treatment. In fact several radiotherapists consider that the B.M.R. is the most

Dysplasia Epiphysealis Multiplex

By H. A. T. FAIRBANK, D.S.O., M.S.

CASES in which several epiphyses have shown irregular ossification have been published from time to time under a variety of titles. Some are undoubtedly examples of one or other of the recognized conditions in which changes in some of the epiphyses constitute a minor feature, while others have been described as multiple osteochondritis, with little to support this diagnosis. With pseudo-coxalgia, a typical instance of osteochondritis, these cases show nothing in common except irregular ossification and flattening of the head of the femur. The progressive changes characteristic of pseudo-coxalgia have not been recorded in the cases under discussion.

It is the purpose of this paper to describe the features of a condition which I believe should be regarded as a clinical entity, and as a developmental error resulting from some unknown cause. It is characterized by dwarfism, stubby digits, and mottling or irregularity in density and outline of several of the developing epiphyses, and it lacks the other abnormalities of the skeleton necessary for its allocation to one of the well-recognized groups. As usual, difficulty has been experienced in deciding whether to include an individual case in the group or relegate it to the scrapheap of unclassified cases. Doubtful cases have been excluded.

The following description is founded on the study of 15 cases, 7 of which have already been published, but only 2 of these under the title of this paper. Cases included have been published under the following titles: Achondroplasia (White, 1924); Epiphyseal Dysostosis (Jansen, 1934); Dwarf with Stippled Epiphyses (Buxton, 1930); Hereditary Deforming Dyschondroplasia (Gardiner-Hill, 1937).

In 1935, in discussing the classification of generalized affections of the skeleton, I ventured to suggest Epiphyseal Dysplasia for the title of a group and briefly reported a case. To this Generalisata was added, but this was altered later to Multiplex, as being more accurate. In 1938 cases under this title were shown before this Society (Wiles and Yarrow respectively).

The features of the condition as found in this series are as follows: It is an affection of children and young people: the ages in this series varied from 18 months to 20 years. One of my cases, first seen at 14 years, has been followed for over twenty years.

It affects both sexes and is not inherited as a rule, but one case, a boy, appeared to have inherited it from his mother, while two sisters are included in our series. Intelligence is usually normal. Some degree of dwarfism, of the short-limb type, is the rule, it being definitely recorded in 13 of the cases. Some enlargement of the epiphyses is occasionally

(C) *Congenital heart disease*.—No heart trouble or cyanosis in early life. (1) *Pulmonary stenosis*: No pulmonary systolic murmur or diminution of the pulmonary second sound. (2) *Septal defect*: The circulatory studies exclude any intracardiac shunt.

(D) *Beri-beri*.—There has been no dietary deficiency.

(E) *Ayerza's disease*.—Gross cyanosis and polycythæmia absent, and normal lung shadows on X-ray.

Dr. Terence East (*Brit. Heart J.*, 1940, 2, 189) described three cases which clinically resembled the above, and which on autopsy showed no gross pulmonary endarteritis or other anatomical cause for the pulmonary hypertension.

A Simple Technique for Capillary Microscopy.—ELI DAVIS, M.D.

The technique of capillary microscopy is disarmingly easy. For a good view of nail-bed capillaries a special capillary microscope is unnecessary. Any good laboratory microscope will do, but a binocular instrument has advantages. A powerful light is concentrated by a lens (5x) on to the nail-bed. I use a table which fits snugly over the microscope platform on which the arm and hand are supported. The table is grooved where the fingers rest. The 2/3 objective is used, and a useful magnification is 60. In most patients washing of the nail-bed is unnecessary, and scrubbing must be avoided. The dry nail-bed is covered with immersion oil.

Technique is easy, but interpretation of what is seen requires experience. Age of the patient and the room temperature affect the capillary pattern. There may be marked differences between the capillaries in different fingers, and even in the same nail-bed. A common pitfall is the observation of a number of patients suffering from some particular disease and then deducing that the capillary picture is characteristic of that disease—without sufficient knowledge of possible variations in normal persons, and the appearances in common diseases. It must be remembered that at the nail-bed only a tiny fraction of the body's capillaries can be seen.

But despite these difficulties capillaroscopy is a useful ancillary aid in the study of human physiology and pathology, and in certain conditions gives useful information—for example in the study of petechiæ formation, Raynaud's disease, atheroma, vasomotor instability, and clubbed fingers.

(Capillary microscopy was demonstrated, and representative paintings of appearances were shown. See figures.)

FIG. 1.—Normal capillaries. FIG. 2.—Petechiæ formation. FIG. 3a.—Capillaries in Raynaud's disease. FIG. 3b.—Raynaud's disease. Same patient as in fig. 3a.

FIG. 4.—Capillaries in atheroma. FIG. 5.—Capillaries in vasomotor instability. FIG. 6.—Capillaries in clubbed fingers. (Paintings by Mr. P. Startup, photographed by Mr. J. E. Andrews. x30.)

Lastly, mottled epiphyses have been described by Traub (1939) in association with pituitary gigantism.

Finally I would suggest that if there is reason to suspect pseudo-coxalgia in a patient below the average in height it is well worth while having films taken of the shoulders and ankles to exclude the developmental error which is the subject of this paper.

I am greatly indebted to friends who have supplied me with details of cases under their care.

Cerebral Palsy

By E. STANLEY EVANS, F.R.C.S.

It is over one hundred years, namely in 1843, since W. J. Little described in a course of lectures at the Royal Orthopædic Hospital, as it was then called, the condition of spastic rigidity of the limbs of newborn children. The lectures were published in the *Lancet*, and more fully in his book published in 1853, on the "Nature and Treatment of Deformities". In 1861 he read a paper to the Obstetrical Society of London "On the Influence of Abnormal Parturition, Difficult Labours, Premature Births and Asphyxia Neonatorum, on the Mental and Physical Condition of the Child especially in relation to Deformities". In less than twenty years in orthopædic practice alone, and here it will be remembered that Little was a physician to the London Hospital, he saw about 200 cases of spastic rigidity excluding idiots in asylums. He dealt at length with the ætiology of the condition, his description of patients suffering from Little's disease was graphic and has never been surpassed, and he laid down certain precise principles of treatment. Although in speaking to the obstetricians he stressed the importance of birth injuries and of neo-natal abnormality, yet in addressing his students of orthopædy he stressed his belief in the pre-natal lack of development of the brain in these cases. Stewart, in his Presidential address to the Neurological Section of this Society, in 1942,¹ emphasized his view that there was no single and specific cause of cerebral diplegia, that birth injury had in the past been assigned too large a part in the pathogenesis, and that the most common cause was primary degeneration of the cerebral neurones as suggested by Collier.

Little gave admirable descriptions of his cases and stressed the frequency of mental impairment, of speech defects, of difficulties in feeding and swallowing, of functional disability of the upper limbs, of constipation and of the typical deformities in the lower limbs. He recognized the association between hemiplegia and epilepsy and realized that mild cases might exhibit no manifestation other than awkwardness, and that in many the intellect was unimpaired.

In his treatment of these patients Little was essentially conservative, and used tenotomy only as a last resort. This is the more interesting when it is remembered that Little introduced the operation of subcutaneous tenotomy into this country after Stromeyer had operated on him with great benefit for the club foot from which he suffered.

Since that time children suffering from Little's disease have usually been passed by the pædiatricians and neurologists to the orthopædic surgeon. The surgeon often performs tenotomies or neurectomies in an attempt to establish muscle balance and thereby still further weakens the limb. This treatment is preceded and followed by physiotherapy and walking exercises. In the orthopædic hospital school attempts are made to educate these children and I think it is true to say that the physiotherapists, school teachers and even the surgeons have often been pessimistic as to the outlook and disappointed with the results, and the question has often been asked: "Are these children worth all the effort and money spent on them?" Here was Little's answer: "I have had many cases under observation from one to twenty years and may mention as an encouragement to other

¹*Proc. R. Soc. Med.*, **36**, 25.

seen. The hands are striking, the fingers and thumbs being short, thick and stubby with blunt ends. Apart from the dwarfism and the shape of the hands, there is no characteristic deformity, but the following were noted: Flexion contracture of some of the joints—knees, elbows and hips—has been present in a few cases, and in one limitation of abduction of the shoulders. In single cases, subluxation of the radial and of the tibial heads was noted. The spine is usually free from deformity. Difficulty in walking or pain and stiffness, particularly of the knees, has been present in several cases.

Radiological findings.—The essential abnormalities are seen in the epiphyses, the centres for which may be late in appearing, backward in development, and slow in fusing with the shafts, but the principal change is irregularity in ossification. They are irregular both in density and shape, being mottled in appearance and perhaps mulberry-like in outline. Separate subsidiary centres around the main centre are common, and this results in some peripheral stippling. There is a definite tendency toward improvement, the epiphyses eventually becoming normal in density, but not in outline, which, though smooth, remains permanently abnormal. Any or all of the epiphyses may be affected, the most common to show typical changes and permanent deformity being the hips, shoulders, ankles and less frequently the knees. The heads of the femora and humeri remain shallow and less convex than the normal. In one typical case the femoral heads at the age of 27 still showed irregularity in outline and partial fragmentation, a condition that might well be mistaken for pseudo-coxalgia, which was in fact the diagnosis made when he was first seen at the age of 14. The femoral neck may or may not be thickened. Some irregularity of the acetabula was present in only 3 cases.

The femoral condyles may show little in the way of abnormal ossification or the changes may be much more marked. In older children striking irregularity in shape is seen in some cases, the condyles being flattened, and inclined to be rectangular in shape. The patella may show decided mottling.

The ankles show changes of diagnostic value. A slight amount of obliquity of the joint is met with occasionally in normal individuals, but in this condition the obliquity is marked. The lower tibial epiphyses diminish markedly in depth from within outwards. The joint line is therefore oblique, and the trochlear portion of the astragalus is misshapen to conform to this.

In 2 cases the capitellum in each elbow shows as a poorly calcified centre with a sharply defined nucleus of much greater density. The metaphyses show no consistent characteristic change, but they may be trumpeted, and the epiphyseal lines irregular. In 1 case the upper humeral epiphysis, very fragmented and irregular, overlapped the neck on the inner side, while the epiphysis for the tibial head lay in an oblique antero-posterior plane, the tibia being subluxated backwards.

The shafts of the long bones are shorter than normal but not thickened as a rule. The carpal and tarsal bones ossify late, and may be very irregular in outline. The metacarpals, metatarsals and phalanges are stunted. The vertebral bodies show no peculiarities as a rule.

The pathology is obscure.

Differential diagnosis.—There are at least seven other conditions, besides osteochondritis, in which the epiphyses may show irregular ossification. The classical signs of cretinism, the first to be excluded, are absent, and there is no improvement in the appearance of the epiphyses in response to treatment.

In dysplasia epiphysealis punctata, as it is now called, or stippled epiphyses, the whole of an epiphysis seems to be ossifying from a large number of discrete centres. The shafts of the bones are short and thick, and the ends splayed. The tarsal bones may be completely stippled. The abnormalities generally are much more gross than in most cases of the multiplex group.

In chondro-osteo-dysplasia of the Morquio-Brailsford type, the femoral heads show striking epiphyseal changes but in this condition the acetabula are markedly enlarged and irregular. Notable features are the abrupt kyphotic deformity in the dorsolumbar region, and the shape of the vertebral bodies; in the latter the central prolongation anteriorly is quite distinctive and diagnostic.

In dyschondroplasia changes in the epiphyses, when seen, are completely overshadowed by the gross abnormality of the metaphyses: they are never seen except when the adjacent portion of the metaphysis contains obvious masses of cartilage.

In osteopetrosis or marble bones, some of the epiphyses may show irregular density or stippling, but the changes in the shafts dominate the picture.

re-training of muscles and improved joint mobility must be sought and attained. Exercises must be graded very carefully until the patient can use the spastic muscles without the development of the spastic stretch reflex and the tone of the weak muscles must be improved. In Phelps' view, operation should only be carried out when structural contractures are present. Little practically enunciated the same principles. It is essential in apathy to gain and maintain a full range of joint movement.

In athetosis the essential element is to train for conscious and voluntary relaxation by Jacobson's methods and to assist in eliminating purposeless movements. In athetoid quadriplegia with tension the attainment of relaxation releases the tension and the athetoid movements become evident. In all doubtful cases this therapeutic test is invaluable in establishing the diagnosis. Ultimately the patient should be able to relax in all positions, starting flat, then on a reclining couch, sitting on a special relaxation chair and so on, and all movements must be carried out with a minimum expenditure of energy from the relaxed position. Records showing progress are kept in the form of graphs.

In the treatment of these children suffering from cerebral palsy, a wide and comprehensive approach from all angles is essential, and treatment must be individual, intensive and progressive. In a Unit such as the one at Carshalton the services of a physiotherapist, occupational therapist, speech trainer, educational psychologist and a school teacher, highly skilled in their several spheres of therapy and conscious of each other's problems, are available. The patients are discussed at a weekly conference of all the therapists, and each must cope with the individual child at the stage and level he has attained. Collectively they must prepare the child physically and mentally so that he can benefit by education, and the school teacher, for example, must not demand of the child a greater effort and standard than that of which he is capable at any particular moment. Periodic (three-monthly) functional joint and muscle examinations are made, and accurate records kept.

In the attainment of all normal skills, gradual progression is essential. Bad habits have to be unlearned and the children trained to acquire the skills in a manner similar to the development of the normal child from infancy, bearing in mind the motor handicap and the absence of the usual sensory and motor experiences of the child suffering from cerebral palsy. For example, in the case of an athetoid child who has to be taught to feed himself reasonably well, conscious relaxation is essential and all movements are performed from the position and state of relaxation. Ultimately the child sits in a relaxation chair with a felt seat, a foot rest and side arms to give security, at a table with a feeding board made with troughs into which a plate and tumbler fit securely, and is assisted in feeding himself with a minimum of effort. He then progresses to use himself a specially adapted spoon, easy to grip and later to use a similar knife and fork. Training is finally completed when a child is able to sit in an ordinary chair, at an ordinary table and use ordinary cutlery.

The same progressive training is necessary in acquiring the skill of walking. Conscious relaxation in all its stages is necessary, and ultimately the child is made to stand in boots fixed to specially weighted skis with poles. The weights, and later the poles, are removed, and the child stands and walks in skis alone. Training is ultimately successful if and when the child is able to stand and walk, for increasing periods, in ordinary boots.

[The type of ski used was shown to the meeting.]

In speech training, progression implies relaxation and correct breathing, vowel production, production of the easiest, and later the most difficult consonants, followed by simple word production. A child satisfactorily rehabilitated can walk and talk at the same time, but it must be remembered that the performance of a double skill at one and the same time represents very considerable attainment. This training will produce results in the educable and co-operative child but no length of treatment can be laid down, as each individual varies in his initial handicap and in his rate of progress. I have not referred to the medical personnel of such a unit but there should at least be a neurologist, a psychiatrist, a paediatrician and an orthopædic surgeon. Operative trauma or therapy should be reduced to a minimum.

50 patients suffering from cerebral palsy have been seen during the past few months, and 22 of these have received, or are receiving, treatment in the Unit. Of the 50 all but 4 had been diagnosed as suffering from spastic disease, and the 4 from various forms of chorea. 25 of the 50 patients were found to be educable athetoids and there were only 2 ineducable athetoids. There were 7 educable spastics only and 13 ineducable spastics. 2 patients were found not to be suffering from cerebral palsy and in 1 the differentiation

practitioners that treatment based upon physiology and rational therapeutics affects an amelioration surprising to those who have not watched such cases. Many of the most helpless have been restored to considerable activity and enjoyment of life."

At Carshalton, where for many years we have been constrained to take these children, much thought and treatment has been expended on them. It was felt to be unwise to segregate them in one or more wards and so they were parcelled out amongst the wards, the physiotherapists and the teachers. The teachers regarded them as an encumbrance and felt in practically all cases that they held back the rest of the class. The children were regarded generally as mentally retarded, were kept in a corner of the ward and given walking exercises, neurectomies and more walking exercises, and the results were most disappointing. Satisfaction was experienced when a child acquired a good stance and was enabled to walk reasonably well. Some did better, or less badly, than others, and a poor result was generally attributed to the lack of co-operation on the part of the mentally retarded patient.

It was with this background that some three years ago I appointed Mrs. Collis as a physiotherapist dealing solely with the spastic child. She is a trained physiotherapist and occupational therapist and had worked with Dr. Winthrop Phelps at Baltimore.

In the Cerebral Palsy Unit at Carshalton we have applied the principles enunciated by Winthrop Phelps and so far as practicable carried out the appropriate regime of treatment.

For over twenty years Phelps has had a remedial school for spastics, and as the result of his researches and experience insists in brief on: (1) an accurate diagnosis of the condition; (2) a careful mental assessment; (3) a wide, comprehensive and intensive approach so far as appropriate treatment is concerned.

His classification on a motor basis of patients suffering from cerebral palsy is: (1) spasticity (quadriplegia, monoplegia, hemiplegia); (2) athetosis; (3) ataxia; (4) tremor; (5) rigidity.

Spasticity, so far as cerebral palsy is concerned, results from a lesion of the cerebral cortex. Spasticity is constant and is the result of hyper-irritability of the spastic muscle to all stimuli. The essential underlying phenomenon is the spastic stretch reflex, which is the uncontrollable contraction of a spastic muscle when its antagonist attempts to contract. I need not enumerate the clinical features.

Athetosis is the result of a lesion of the basal ganglia and the involuntary movements interfere with normal movements. Phelps subdivides this group into non-tension and tension athetosis. We are all familiar with non-tension athetosis in which the involuntary irregular movements are either rapid or wormlike. In tension athetosis, tension develops secondarily in an attempt to control the athetoid movements—at first voluntary, the tension later become habitual. Tension is usually mistaken for spasticity but there is no spastic stretch reflex. To all intents and purposes the child suffering from athetoid quadriplegia with tension is indistinguishable from the child suffering from spastic quadriplegia unless the condition is sought and recognized. It is vitally important to make this distinction because the treatment and prognosis are different. In our small series, over 50% of patients labelled "spastics" have been found to be suffering from athetosis with tension.

In spastic diplegia there is more likelihood of mental retardation because the lesion is in the cerebral cortex, whereas in athetoid quadriplegia with tension, the lesion is in the basal ganglia and the great majority of the patients are of reasonable or average mentality. It must be remembered that the usual intelligence tests, for example the Stanford-Binet tests, require language and motor skill and due allowance must be made, by the psychologist who understands cerebral palsy, for the difficulties inseparable from the severe motor handicap. The object of mental assessment is to estimate how far a child suffering from cerebral palsy is trainable and teachable. At Carshalton, less than 10% of the athetoids and over 60% of the spastics were found to be ineducable.

The purpose of treatment is (1) to estimate economic potentiality, (2) to make the child independent or semi-independent. Even if unable to earn his own living the patient suffering from cerebral palsy should be able to care for himself and care for his personal needs. Stress is laid on speech training as a means of communication, on hand and arm usefulness, on locomotion and on personal appearance so that the patient may become socially presentable. I cannot, in this short paper, deal with the details of treatment but can only stress certain features.

In spasticity too much attention should not be focused on the spastic muscles, for others are found to be weak and some flaccid. Conscious and voluntary relaxation, the specific

TREATMENT

These cases all came under my care at the Kettering General Hospital, and it was fortunate that I was able to see them on, or soon after, admission.

CASE I.—A farm labourer, aged 56. His accident occurred in December, 1944. He had a very swollen knee-joint.

He was not very shocked and I was soon able to take him to the theatre. A Kirschner wire was inserted into the upper end of the tibia, and manual traction applied. An Esmarch's bandage was then applied to compress the condyles into position. After this was removed it was replaced by a pressure bandage with wool. The extension was tied to the end of a Thomas' splint, which was slung up on a Balkan beam on his return to the ward.

This was left for six weeks, and then the wire was removed and replaced by a strapping extension with the leg straight for a further period of six weeks. He was then given a walking caliper and allowed to go home. There was no movement in the knee-joint.

He attended a class for knee exercises for many weeks but without result, and I had expected his knee to be full of adhesions so I was not disappointed. He stopped attending about last June, but he has come up to see me when I have specially sent for him. His end-result is a stiff stable knee.

CASE II.—This was a girl, a clerk aged 22, and she was admitted on June 3, 1945. Her fracture was compound, but her general condition was good.

Within an hour of admission, the leg was cleaned up and a Thomas' splint was slid up the leg. A strapping extension was then applied below the knee, and the area of operation carefully prepared. I commenced by nibbling away the dirty end of the shaft of the femur, and then manual extension was applied. The wound was dealt with in the usual manner, all damaged muscle being excised. The condyles were much more comminuted than would appear from the X-ray films [shown], but they were put in as good a position as I could obtain, the wound dusted with sulphanilamide powder, and lightly packed with vaseline gauze, and a dressing applied. I had considered putting in a long screw to fix the condyles, but I could not see that any screw could have got a satisfactory hold in such a comminuted bone; and anyway I was opposed to putting any screw into such a wound if it could be avoided. A plaster cast was then applied over the dressing with light wool padding from the ankle to the groin. A window was cut in the plaster for subsequent removal. The extension was transferred to the splint and the splint slung up on a Balkan beam on return to the ward.

She was given 15,000 units of penicillin every three hours intramuscularly for the next five days, and she was fairly comfortable. At the end of a week I again took her to the theatre without disturbing the splint, and under pentothal anaesthesia removed the window and inspected the wound, and found that it looked healthy. A swab was taken and it was sterile on culture. As much as possible of the wound was drawn together with silk worm sutures, but no tension was applied. Again a week later I took her to the theatre and again took a swab, which proved sterile. I removed the sutures and put a split skin graft into the remaining part of the wound. When again inspected in ten days the wound was healed, except for a slight serous discharge from the depression.

This patient did run a slight pyrexia for almost six weeks, but the temperature was never over 100°, and her general condition was excellent all the time. Extension was maintained for twelve weeks, and then she was given a light plaster with a walking caliper. She is still wearing the caliper and she is quite comfortable in it, but she has some pain if she tries to leave it off. Her knee-joint has a few degrees of flexion, and she has not the power of complete extension, and she has some lateral instability.

CASE III.—A Land Army girl aged 19, admitted on June 16, 1945. The wound was almost identical with the previous case, and she was given exactly the same treatment. Her wound was quite dry and healed in three weeks, and she never showed any pyrexia. Though the reduction shown in her films would lead one to expect a poor result, she has the better knee of the two. The film also showed a transverse fracture of the patella low down.

She is regaining a fair degree of flexion and she has a slight medial instability, but she is able to walk quite well without her caliper, and without any discomfort.

CONCLUSION

These cases illustrate what we may call a typical "Pillion Fracture". The treatment carried out illustrates the value of the recent advances in technique—careful wound toilet, penicillin, and early closure by secondary suture and/or skin graft—so reducing what was once a formidable compound fracture to a routine procedure.

I am not, however, trying to demonstrate the correct treatment and reduction of the fracture, or brilliant end-results.

It was my privilege to take part in an orthopædic team under the E.M.S. following the invasion of Europe, and I would like to express my acknowledgment and gratitude to all those who have been responsible for our modern conception of treating compound injuries. I wish also to express my thanks to our Consulting Orthopædic Surgeon, Mr. Leslie Morris, of Leicester.

between spasticity and athetosis with tension could not be made until the child had been under observation for several weeks.

Of the results, I can at present say but little, because an assessment committee of experts is reviewing the value of the work, but I can say that in my view the results have far exceeded my expectations and are better than I personally could have obtained by orthodox methods.

CONCLUSIONS

In order to obtain the optimum results in dealing with children suffering from cerebral palsy the following factors should be borne in mind.

(1) An accurate diagnosis must be made particularly to ensure that patients suffering from athetoid quadriplegia with tension are not confused with those suffering from spastic disease.

(2) A careful mental assessment must be carried out in order to exclude those patients who are ineducable. Some by virtue of mental impairment or because of very severe motor handicap will be capable of partial rehabilitation only.

(3) Generally, the younger the patient the better the prognosis. The 8 months' old infant has less to unlearn and will make more rapid progress, other things being equal.

(4) Operative treatment, in Phelps' view, should be confined to the release of structural contractures in spastic cases, and should not be carried out in patients suffering from athetosis with tension.

(5) Epilepsy is of serious import and such patients should be excluded.

(6) Complete comprehensive and intensive treatment should be carried out in the selected cases, selected because they are educable and not because they have slight motor handicap. Co-ordination of effort between the physiotherapist, occupational therapist, speech trainer, school teacher, psychologist and the medical personnel is essential.

(7) There are thousands of children suffering from cerebral palsy in this country and the time is ripe for the establishment of a number of residential remedial schools as trained staff become available. These must be primarily *not* educational establishments, but centres where children suffering from cerebral palsy can be treated and trained from the physical and mental aspects, and be prepared to such a stage of rehabilitation, that they can benefit by education.

Finally, I must express my appreciation of the work done in this Unit by Mrs. Collis and by Dr. Winthrop Phelps whose principles and practice have, so far as possible, been followed.

Pillion Fractures

By FRANK RADCLIFFE, F.R.C.S.

PILLION fracture is a comminuted T-shaped fracture of the lower end of the femur, with separation of the condyles, and displacement of the condyles behind the shaft of the femur. Recently I have had 3 cases of these fractures all of which occurred in the knees of pillion riders.

In the first case, which was a closed fracture, the shaft was displaced down between the condyles and it was not far from the articular surface of the tibia. In the other two there was a fairly extensive wound with the end of the shaft protruding through the skin and lying over the patella.

Mechanism.—The three accidents all occurred the same way, that is to say, motor cycle and pillion rider being involved with a motor lorry in collision, and by coincidence, in the second and third case with a petrol tanker. As far as I can say the motor cycle had almost avoided the lorry on rounding a corner when the knee of the pillion rider, in a typical position that I need hardly describe, took the whole weight of the impact.

I suggest that the force came against the patella, which was driven almost like a wedge against the condyles of the femur, splitting them apart and detaching them from the shaft, and then the leg, knee, and condyles were driven up under the shaft.

Section of Epidemiology and State Medicine

[November 23, 1945]

The Epidemiology of the 1945 Outbreak of Poliomyelitis in Mauritius [Summary]

By ALLAN M. MCFARLAN, M.A., M.B., B.Chir.

Emergency Public Health Laboratory Service, Cambridge

DURING the first five months of 1945 there were at least 1,018 cases of poliomyelitis in Mauritius. The attack rate was 2.4 per 1,000 of population. In 851 cases there were 64% under 5 years of age and 95% under 10. Only some 4% of the cases were without definite paralysis. In 86% the legs were affected. The dromedary type of temperature curve was present in some cases, and the suggestion is made that the first rise of temperature may correspond to an illness of infection and a period of infectivity.

The epidemic began in February, shortly after a cyclone had caused widespread damage to houses. There was an increasing prevalence of intestinal diseases at the time and it is suggested that the virus of poliomyelitis during passage from a few sporadic cases which occurred in January or from symptomless excretors underwent a mutation and became more invasive and more pathogenic.

The weekly incidence of cases showed a very symmetrical and somewhat steep curve resembling that of an influenza epidemic. The character of the curve suggested an infection with a very short incubation period and a high degree of infectivity. Paralytic poliomyelitis does not have these characteristics, but they might apply to a carrier epidemic of the virus. A short period of infectivity in carriers beginning two or three days after infection would lead to an epidemic curve of the explosive type and the much smaller but similarly explosive curve of cases of paralysis would follow a week or ten days later. Casual contact apparently sufficed to transmit infection, and for this and other reasons the presence of the virus in the pharynx may be more important for the spread of infection than its presence in faeces.

The outbreak was at first localized to one area but spread rapidly all over the island. The spread from place to place appeared in a number of instances to be by healthy adult male carriers. Subsequent spread was mainly by further carriers both adults and school children. Sanitary arrangements were very bad, particularly after the cyclones, and flies were abundant, so that flies might have transmitted infection to a few cases. Only one village had an explosive type of epidemic and there the contamination of ices possibly played a part in the spread of infection. In other villages the type of epidemic suggested a spread by transient carriers.

An Analysis of the Failures of the Smith-Petersen Operation for Fracture of the Femoral Neck

By G. O. TIPPETT, F.R.C.S.

THE speaker described briefly his treatment for these cases of fractured neck of the femur. In the series under review all the cases had been subjected to operation during the period of the last two years. They were divided for purposes of treatment into age groups of over 70 and under 70. In the over-70 group the patients were often severely shocked by the trauma of the injury and unless quickly freed from pain and got out of bed they became bedridden with a poor prognosis of life. In these cases he inserted a Smith-Petersen nail only. He stated that often he inserted a long nail which might protrude through the head of the femur for about a quarter of an inch. If this protrusion was low down on the head, the hip was not arthrodesed and surprisingly little pain resulted. The advantage of this long nail was to secure the maximum grip on the small central fragment of the fracture, so that the patient could be sat up right away and got out of bed within a few days sitting in a chair or walking with crutches. He advocated this measure as a life-saving measure without thought of damage to the joint. For those cases under 70 he performed a Smith-Petersen nailing together with a fibular graft. The advantage of this procedure was that one got a double hold on the fracture fragments. The causes of failure were: (1) due to the fracture itself, and (2) due to the treatment. In (1) the fracture occurred nearly always in later life with inevitable shock. In (2) the failures could be divided into avoidable and unavoidable. The avoidable failures were produced by (a) sepsis, introduced at the time of the operation or late autogenous sepsis giving rise to infection of the hæmatoma or round the nail after some months. (b) Poor placing of the nail. He stressed that the nail must be placed in perfect position with perfect centralization of the nail as shown in two planes by the X-ray films. This was especially necessary when the nail was accompanied by a graft. (c) Extrusion of the nail. This might be a normal process due to shortening of the neck owing to further impaction during the process of union of the fracture, and thus the speaker deprecated the use of a nail with a cross-pin in its base as this held open the fracture line. (d) Avascular necrosis of the head of the femur. This might be due to roughness of the surgeon in reducing the fracture or to damage caused by the mechanical instruments perforating the neck and head of the bone during his operation of nailing. Likewise too early a weight-bearing may damage a head the vitality of which is only just secure, but which would have lived if the trauma of weight-bearing had not been added at too early a date. The unavoidable cases are those of avascular necrosis outside the ability of the surgeon to prevent. In these cases it was part of the penalty of breaking a bone at a site where nature had given a poor blood supply, and death was from shock and old age.

The speaker illustrated these causes of failure by quoting a series of cases that had come into his clinic during the last two years both from his own operating and those of other surgeons. X-rays were shown to illustrate the points.

tion, for example, can be related to the feeding of babies and animals; respiration to ventilation; and reproduction to pets. At this stage, too, health teaching can be illustrated and health morals drawn from the lives of the great.

Between the years of roughly 11 to 16, factual human biology should be the background of health education. *Homo sapiens* will be much more interesting at this stage than the amoeba. Sex instruction must not be omitted, of course, but there should be no over-emphasis of it. The reproductive system and the function of reproduction should be considered as a part of the structure and functions of the body as a whole. In addition to this *ad hoc* health instruction, health teaching should permeate every other subject. For instance, the class might study the history of the growth of the health services; school outings might include visits to see the health services at work. A visit to the sewage farm is surely no less important than a visit to a museum; and discussions on the work of the school doctor and the school dentist and the contribution that they can make to health can be tied up with their visit to the school.

The health education of the adult is the most difficult of all. Old wives' tales have to be debunked and faith in the bottle of medicine shaken. Although we may deplore the interest in disease, we must try to make use of it. For the present generation of adults, therefore, we must often start off our teaching from this interest, teaching physiology under the guise of pathology.

The material we use to assist us in our health education work must be carefully related to our purpose. The leaflet and poster are much less effective than the film, which makes a direct appeal to every section of the community. In the early stages of health education films, there was an attempt—often a somewhat heavy attempt—to create a melodramatic story. The more recent trend is towards a straightforward presentation of health facts which are themselves of sufficient interest to hold the attention of the audience. This move is in the right direction. Exhibitions can attract large numbers of people but it is doubtful if they really change habits or attitudes. They warm the feet but not the heart. There is an immense ready-made audience for health education in our factories and this is a field which should be increasingly cultivated in the future. The lecture carries a direct message, personally delivered, and offers an opportunity for answering questions. Its great disadvantage is that it attracts the converted. The lecture too is sometimes less effective than it might be because the lecturer is often a crank. It is essential that health lecturers should be notably sane. Their lectures should be clearly based upon a wise and common-sense philosophy, and there should be no sign of exaggeration or undue bias.

The most effective health education is personal health education passed on by direct contact. The doctor, the teacher and the health visitor have a great opportunity here. All three, however, have much to learn about the content and methods of health education if they are to play their potential part to the full. The training of the doctor and nurse in the past has itself been much more concerned with disease than with health and most of us would find ourselves hard-pressed to enumerate more than a few health principles. We must build up our knowledge of the physiology of healthy living until it surpasses our knowledge of pathology, and we must see that it is passed on to all those people who are in positions of authority. We must learn too how we ourselves can put this knowledge across in an interesting and inspiring way to those whom we are in a position to influence.

The radio is a health education medium of importance. Only a few facts should be included in each talk and these should preferably have some direct bearing upon the lives of the hearers. The talk that is overcrowded with facts will fail to strike home. A short talk is better than a long one. The appeal to the hearer should be personal and the language simple, straightforward and unadorned. The possibility of misinterpretation should never be forgotten. In this sense the spoken word is more dangerous than the written because one cannot turn back to see exactly what was said. If the radio talk is to be lively and direct it must be dictated and not written. The talk that is laboriously produced in polished writing will not read well on the radio, but will seem stiff and stilted and will make real contact with the audience impossible.

If health education is to develop as it should, it must have the right set-up and machinery. This is a field where voluntary or quasi-official organizations can do better work than Government Departments. The war has shown that people are

The most important factor determining infection was contact. Families with a case of poliomyelitis had a higher percentage of adult males in occupations with contacts outside the village than did the population of the district as a whole, and also a higher percentage of children attending school. In rural districts the attack rates increased with increasing population density. Attack rates were higher in boys than in girls particularly in towns; in Chinese children than in Indian children; in persons in the same family than in the general population. The chances of exposure were greater in the groups with the higher attack rates.

Recent American work has shown that the distribution of faecal excretors of virus during an epidemic is concentrated around cases, as would be expected from faecal spread. However, the distribution of cases of poliomyelitis in Mauritius and in other epidemics has been more diffuse and suggestive of a spread by pharyngeal secretions. At present the measures taken to limit the spread of poliomyelitis should be those used in meningococcal meningitis to prevent respiratory spread and also those used in Sonne dysentery to prevent faecal spread.

The work reported here was done in collaboration with Professor H. J. Seddon and Major G. W. A. Dick, R.A.M.C.

Popular Health Education

By CHARLES HILL, M.A., M.D., D.P.H.

HEALTH Education must take account of existing prejudices and resistances. It is unfortunate but true that the public is more interested in disease than in health; that it would rather put its faith in a bottle of medicine to cure disease than make the adjustments of life that are necessary to improve health; and that it prefers to be guided in its approach to health and disease by the old wives' tales picked up during childhood than by the latest scientific knowledge. In general, there is a profound ignorance of the working of the human body and any knowledge of physiology which is possessed is drawn almost entirely from patent medicine advertisements, which introduce the public to such physiological truths as the "acid in your stomach will burn a hole in the carpet" and to the concept of "night starvation". As a consequence of these attitudes and influences, the middle-aged are fixed in their habits and encrusted in an almost impermeable shell of folk-lore. To get results, therefore, we must concentrate on teaching the young the healthy habits and the knowledge that can be for them the basis of their healthy living.

In teaching the young there are certain principles that must be borne in mind. Perhaps the most important, and probably the most universally disregarded, is that parents should answer the questions of their children truthfully and without any signs of embarrassment. The fact that a child asks a question on any matter is a sign not only that he is interested—which will, of course, mean that he is also receptive—but that he is intellectually ready to receive the information for which he asks. If, therefore, his questions are answered as they arise—no more but no less—his health education, including his sex education, will proceed in a natural manner. Of course it is desirable that the essential biological facts should be taught systematically as well, and the facts of reproduction should certainly be taught as part of biology before the age of 12. In this way they will become an accepted part of the child's background of knowledge before he has become himself emotionally involved. At all costs, we must avoid making health education appear a set of dreary "don'ts". Our approach must be the inspiring one of stressing the beauty, grace and joy of a positive attitude to health.

Our health teaching must be graded to suit the intellectual level of the people taught. In the case of a pre-school child and a young child up to the age of, say, 7 years, we should be content to teach the proper habits without explanations unless, of course, explanations are asked for. At this stage it is more important for the child to learn to do the right thing, even imperfectly, as a routine part of life than to be expert in and knowledgeable about the right method of doing it. During the next four years or so up to the age of about 11 there should be a gradual development of factual biological teaching based upon the natural interests of the child. Teaching of nutri-

tion, for example, can be related to the feeding of babies and animals; respiration to ventilation; and reproduction to pets. At this stage, too, health teaching can be illustrated and health morals drawn from the lives of the great.

Between the years of roughly 11 to 16, factual human biology should be the background of health education. *Homo sapiens* will be much more interesting at this stage than the *amœba*. Sex instruction must not be omitted, of course, but there should be no over-emphasis of it. The reproductive system and the function of reproduction should be considered as a part of the structure and functions of the body as a whole. In addition to this *ad hoc* health instruction, health teaching should permeate every other subject. For instance, the class might study the history of the growth of the health services; school outings might include visits to see the health services at work. A visit to the sewage farm is surely no less important than a visit to a museum; and discussions on the work of the school doctor and the school dentist and the contribution that they can make to health can be tied up with their visit to the school.

The health education of the adult is the most difficult of all. Old wives' tales have to be debunked and faith in the bottle of medicine shaken. Although we may deplore the interest in disease, we must try to make use of it. For the present generation of adults, therefore, we must often start off our teaching from this interest, teaching physiology under the guise of pathology.

The material we use to assist us in our health education work must be carefully related to our purpose. The leaflet and poster are much less effective than the film, which makes a direct appeal to every section of the community. In the early stages of health education films, there was an attempt—often a somewhat heavy attempt—to create a melodramatic story. The more recent trend is towards a straightforward presentation of health facts which are themselves of sufficient interest to hold the attention of the audience. This move is in the right direction. Exhibitions can attract large numbers of people but it is doubtful if they really change habits or attitudes. They warm the feet but not the heart. There is an immense ready-made audience for health education in our factories and this is a field which should be increasingly cultivated in the future. The lecture carries a direct message, personally delivered, and offers an opportunity for answering questions. Its great disadvantage is that it attracts the converted. The lecture too is sometimes less effective than it might be because the lecturer is often a crank. It is essential that health lecturers should be notably sane. Their lectures should be clearly based upon a wise and common-sense philosophy, and there should be no sign of exaggeration or undue bias.

The most effective health education is personal health education passed on by direct contact. The doctor, the teacher and the health visitor have a great opportunity here. All three, however, have much to learn about the content and methods of health education if they are to play their potential part to the full. The training of the doctor and nurse in the past has itself been much more concerned with disease than with health and most of us would find ourselves hard-pressed to enumerate more than a few health principles. We must build up our knowledge of the physiology of healthy living until it surpasses our knowledge of pathology, and we must see that it is passed on to all those people who are in positions of authority. We must learn too how we ourselves can put this knowledge across in an interesting and inspiring way to those whom we are in a position to influence.

The radio is a health education medium of importance. Only a few facts should be included in each talk and these should preferably have some direct bearing upon the lives of the hearers. The talk that is overcrowded with facts will fail to strike home. A short talk is better than a long one. The appeal to the hearer should be personal and the language simple, straightforward and unadorned. The possibility of misinterpretation should never be forgotten. In this sense the spoken word is more dangerous than the written because one cannot turn back to see exactly what was said. If the radio talk is to be lively and direct it must be dictated and not written. The talk that is laboriously produced in polished writing will not read well on the radio, but will seem stiff and stilted and will make real contact with the audience impossible.

If health education is to develop as it should, it must have the right set-up and machinery. This is a field where voluntary or quasi-official organizations can do better work than Government Departments. The war has shown that people are

suspicious of official advice on health. They fear that it may not be disinterested, that it is an attempt to force upon them something that the Government desires them to accept for reasons other than those purely concerned with their individual well-being. Health education, too, should be free from political bias or pressure, and to be effective must always be a little—although not too much—in advance of public opinion. For all these reasons the proper line of development is for the Government to entrust health education to some such body as the Central Council for Health Education, which is the existing agent of the Government and the Local Authorities in England and Wales.

If health education is to be carried out along scientific lines, the needs and the results must be constantly assessed. This has already been done in a number of instances by the War-Time Social Survey of the Ministry of Information, and valuable information has been gained. There is a real need, however, for a systematic assessment of public opinion on matters affecting health, and for a study of existing health habits. Upon this study we can base our health education programme. And, finally, we must measure the relative efficacy of different media and the result of all our work by assessing the changes that have been brought about in health habits, attitudes and opinions.

Dr. N. M. Goodman said that considerable attention had been paid by the Health Division of UNRRA to the possibility of assisting popular health education in the countries in Europe in which UNRRA was operating. He had reluctantly come to the conclusion that health propaganda could not be exported and must be based on local conditions and originated in the country concerned. He also drew attention to the lack of co-ordination in this country in the teaching of preventive medicine, including health education, to medical undergraduates.

Dr. Robert Sutherland said that health education was a problem in education and not in propaganda: it must be something that coloured the whole life of the individual. It followed that it was best carried out by people who in the course of their day-to-day work were in a position to influence for better or for worse the attitudes, habits and knowledge of others. Amongst these, the parent was, of course, outstanding, and he would like to add the parent to Dr. Hill's group of doctor, teacher and health visitor. The Central Council for Health Education attached great importance to this health education of the natural health educators and, at the request of local authorities, was giving courses in the content and methods of health education throughout the country to such groups, and to midwives, district nurses, school nurses, industrial nurses, and industrial welfare workers.

Nevertheless, although the leaflet, the poster and the press advertisement were less effective than this personal health education, they were of some value, particularly in support. Leaflets, for example, were most effective if they were distributed following a lecture or to support advice given individually by a doctor or a nurse. The best results would be got from health education if there were a carefully integrated use of all media. They all had their time and place and had more effect used jointly than severally. Health education along those continuous and planned lines could undoubtedly make a real contribution to the improvement of individual and community health.

Retropubic Prostatectomy

By TERENCE MILLIN, F.R.C.S.

RETROPUBIC prostatectomy, albeit a British product, is, I believe, the most universally applicable operation yet devised to eliminate the evils of the obstructing prostate. It has its faults, no doubt. What operation in the whole realm of surgery has not? After an experience now of some 85 cases, I am more than ever convinced that it gives me better results than any other I have tried, for every type of case, excluding the fibroses, where, I believe, endoscopic resection reigns supreme.

Before abandoning operations which, you may say, have served us well in the past, we must be reasonably satisfied that the new is better. It is agreed that far too many cases come to us too late, but until we can offer the prostatic patient an easy and relatively safe cure for his troubles, he will not come early, nor indeed are we justified in advising early operation. The present state of affairs is a vicious circle.

In assessing the results of any operation one has to consider mortality, the post-operative course—not only from the surgeon's view-point, but also the patient's—and finally the long-term result.

Mortality.—As far as I know no one in this country has yet published his mortality figures for the Harris operation over an extended series of cases. Through the courtesy of the Staff of St. Peter's Hospital, where most accurate records are kept, I am at liberty to state that the mortality rate for the modified Harris operation during the years 1938-39 was rather more than 10%. These would appear to compare unfavourably with Harris's Australian figures, but there seems to be little doubt that the cases met with here are poorer surgical material than those in the Dominion, and I have it from other Australian surgeons that they cannot approximate to Harris's published results. Mortality figures depend so much on the surgeon's selection of cases.

In the two-stage Freyer technique considerably more die from the preliminary cystostomy than from the subsequent prostatectomy. Cystostomy, simple operation though it be, carries a very appreciable mortality, figures ranging from 4 to 20% if considered over a large enough series to be statistically significant. Again to quote St. Peter's Hospital figures, out of 53 cystostomies, carried out in cases of prostatic obstruction during the years 1938-39, 10 died—a mortality rate of 19%. The second-stage procedure averages out with a mortality rate of 4% in the best hands. It must also be reckoned that a number are left to lead a miserable existence wearing a suprapubic tube, deemed unfit to stand

the rigours of a prostatectomy. The mortality rate of the two-stage Freyer technique is about 8%. In the transurethral techniques, when competence has been acquired (and this is a lengthy process) the immediate mortality should be lower. In my last 200 cases I lost 8. I have had better series, but all in all the death-rate has been about 4%.

Barrington published the St. Peter's figures for prostatic surgery for the five years 1934-38, and reported in 582 cases a mortality rate of 9.07%. Cabot from the Mayo Clinic reported a death-rate of 9.51% in 600 open operations for prostatic obstruction. Here is a table showing my own results where a selection of methods was employed. It is, of course, also a more recent series, where ancillary aids such as sulphur drugs, blood banks, &c., were available.

357 CASES OF PROSTATIC OBSTRUCTION.

Type	Number	% of total	Deaths	Mortality rate
Harris	63	18%	3	4.8%
Freyer (including cystostomy) ...	73	21%	6	8.2%
Endoscopic resection... ..	219	61%	9	4.1%
Radical perineal	2	—	0	—

Total mortality rate for 357 consecutive cases, 5.0%

Post-operative course.—The possible complications of the Freyer technique are well known. This 45-year-old operation fulfils few of the canons of modern surgical technique. The post-operative course is very uncomfortable, and by no means short.

The post-operative course of the Harris case is in general much easier than that of the Freyer, provided that the hæmorrhage has been controlled on the table, and that frequent disturbing wash-outs are not required to maintain free catheter drainage. The same remarks apply to the resection case. I learn that it is common in the clinics of those utilizing the cold punch technique for the unfortunate patient to be disturbed every few minutes for bladder lavage. My own practice when employing the Harris technique was to use a suprapubic catheter for two to four days with continuous irrigation. In resections I use the loop technique in preference to the punch, control the bleeding reasonably well on the table, and then rely on a No. 24F gum-elastic catheter for forty-eight hours to take care of the post-operative oozing. Again bladder lavage is the exception. The post-operative course of the retropubic case is incomparably easier than any of the other open operations.

Late results.—The end-results of the Freyer are on the whole excellent, but shelf formation does occur in a proportion of cases. Even the excision or punching out of the posterior lip of the bladder neck does not guard against this.

The Harris operation carries its own particular late complications. I have already mentioned in a communication to this Section the truly dreadful post-operative obstruction one meets with occasionally after Harris suturing in which the whole prostatic urethra is strictured. There is also a quota of meatal and other urethral strictures when a relatively large catheter has been employed for ten to fourteen days. Another complication, seldom mentioned, which I find occurs not only in my own cases but in those of other surgeons, is a degree of incontinence lasting for a variable number of weeks. These usually clear up, but I have had to deal with two cases of persistent incontinence from other clinics.

Of the late results of the transurethral resections I must speak at greater length. These operations, loop or punch, have proved of inestimable value in dealing with many types of prostatic obstruction, especially the fibroses. They appeal to the public in that no external cutting is involved, and the hospital stay is short. I can claim, I think, a wider experience of these operations than anyone in this country. I have long been an ardent advocate of their use in the lesser obstructions, the poor risk case, &c., but with a full realization that they had their limitations, or rather should have. The transurethral resection cannot be a complete adenectomy despite claims to the contrary. The bogies of recurrent obstruction and persistent infection are ever present. I have a number of patients now resected more than ten years ago, who have had no further trouble, but other cases have not been so fortunate. I have always admitted this, but felt that in many cases the alternative was unduly hazardous, and that it was better to be alive with the risk of recurrent obstruction than dead, cured. To my mind, the greatest bugbear of resection is the risk of subsequent urethral stricture. Early in my urological career I learned that it was unsafe to pass an unduly large instrument along the male urethra. The commonly used Thompson Punch, euphemistically calibrated 30F, is doing irreparable damage. I have recently had 3 members of one London club, resected in the same clinic, all with the most appallingly strictured urethræ. Two of them, by the way, had

two resections at approximately three months' interval, indicating that the complete prostatectomy claimed by the ardent advocates is evidently not so complete. All these men face the picture of monthly bougies for the rest of their lives. One has also recurrent prostatic obstruction. These represent therapeutic disasters. I personally never exceed a No. 28F instrument, and in a number of cases even this cannot be safely passed, a perineal urethrostomy being necessary. Reed Nesbit, one of America's leading resectionists, is, I understand, now employing a urethrostomy in 25% of his cases.

Of the sequelæ of the perineal operation I shall not say much. It has never had a great following in this country, and even in America its advocates are dwindling. You all know the ghastly messes which can occur even in the best hands. I have recently had a pitiful letter from a patient who was subjected to a perineal prostatectomy at the age of 37. Now, fourteen months later, he is still in hospital with a leaking suprapubic fistula, a colostomy, a urethrorectal fistula, and a perineal sinus. There appears to be a slight tendency to return to the perineal route in some quarters quite recently, no doubt due to a dissatisfaction with the accepted suprapubic procedures, and a glib acceptance of certain published figures which scarcely convey the whole truth.

That the enucleation of a simple tumour should entail such hazardous adventures appeared to me to be a blot on modern surgical achievement. I for one had a sense of frustration; I sought elsewhere. The subpubic operation mentioned by Uteau and Leroy proved impracticable. Noting the excellent exposure of the prostate during the operation of cystectomy, I turned to the retropubic approach. From the very first I have been pleased with this. It is virtually a perineal type of prostatectomy performed well away from the rectum and compressor urethræ—the twin bogies of the inferior approach. Moreover, the nerves and arteries of chief moment are situated posteriorly, the anterior aspect of the prostate being accessible without damaging structures other than veins. Anteriorly also the urethra is closest to the surface of the gland, and the ejaculatory ducts are less liable to damage than in the perineal operation. It does not seem to be sufficiently appreciated that the level of the internal meatus is approximately the upper limit of the pubis in the vertical position, and is even higher when there is marked prostatic enlargement and elongation of the prostatic urethra. The retropubic exposure is thus not via a dark, deep, and dangerous hole, as has been suggested by some. The normal anatomy of the approach presents no structures of importance which need be sacrificed. Venous bleeding during the sectioning of the prostatic capsule can be troublesome if adequate care is not taken to deal with these veins, either by ligature or appropriate clamp before division. With the technique I use to-day this bleeding is usually negligible. Three arterial anomalies may be met with, and should be known. I am indebted to my assistant, Mr. Ashton Miller, F.R.C.S., for researches into this subject.

(a) *Accessory pudendal artery*.—This is a sizable vessel which may be met with on the lateral surface of the prostate. According to Buchanan it is only present occasionally, and arises from the intrapelvic portion of the internal pudendal, or from the inferior vesical artery. It passes forward along the lateral aspect of the bladder and prostate to the triangular ligament, which it pierces, branching into deep and dorsal arteries of the penis, and, rarely, the artery of the bulb.

(b) *The dorsal artery of the penis* occasionally arises from the obturator artery close to the entrance of the obturator canal, whence it passes over the posterior aspect of the pubis to reach and pierce the triangular ligament.

These vessels might be injured either during the initial sectioning of the prostatic capsule, or later during the suturing process.

(c) *Aberrant obturator artery*.—This is a better-known anomaly, occurring, according to Gray, in 28% of subjects. It replaces the normal artery, and arises from the deep epigastric of the same side near its origin, passing behind the lacunar ligament, and downwards to the obturator canal. It does not itself lie close to the scene of operation, but the vesical branch normally arising from the obturator artery in the pelvis may spring from this anomalous vessel, and pass via the pubo-prostatic ligament and antero-lateral aspect of the prostate to the bladder.

Now as to the so-called internal sphincter. The classical transvesical procedure entails the division of this structure first with the finger, and later during the delivery of the lateral lobes into the bladder. It is well known that stretching any sphincter entails shock. Moreover, post-operative urethrograms show that in a large proportion of cases the bladder neck remains patulous, and the patient is entirely dependent on the compressor urethræ for continence. Some go a stage further, and fearing a shelf formation due to fibrosis following sepsis, excise or punch out a wedge of trigone, a completely unphysiological

the rigours of a prostatectomy. The mortality rate of the two-stage Freyer technique is about 8%. In the transurethral techniques, when competence has been acquired (and this is a lengthy process) the immediate mortality should be lower. In my last 200 cases I lost 8. I have had better series, but all in all the death-rate has been about 4%.

Barrington published the St. Peter's figures for prostatic surgery for the five years 1934-38, and reported in 582 cases a mortality rate of 9.07%. Cabot from the Mayo Clinic reported a death-rate of 9.51% in 600 open operations for prostatic obstruction. Here is a table showing my own results where a selection of methods was employed. It is, of course, also a more recent series, where ancillary aids such as sulphia drugs, blood banks, &c., were available.

357 CASES OF PROSTATIC OBSTRUCTION.

Type	Number	% of total	Deaths	Mortality rate
Harris	63	18%	3	4.8%
Freyer (including cystostomy)	73	21%	6	8.2%
Endoscopic resection... ..	219	61%	9	4.1%
Radical perineal	2	—	0	—

Total mortality rate for 357 consecutive cases, 5.0%

Post-operative course.—The possible complications of the Freyer technique are well known. This 45-year-old operation fulfils few of the canons of modern surgical technique. The post-operative course is very uncomfortable, and by no means short.

The post-operative course of the Harris case is in general much easier than that of the Freyer, provided that the hæmorrhage has been controlled on the table, and that frequent disturbing wash-outs are not required to maintain free catheter drainage. The same remarks apply to the resection case. I learn that it is common in the clinics of those utilizing the cold punch technique for the unfortunate patient to be disturbed every few minutes for bladder lavage. My own practice when employing the Harris technique was to use a suprapubic catheter for two to four days with continuous irrigation. In resections I use the loop technique in preference to the punch, control the bleeding reasonably well on the table, and then rely on a No. 24F gum-elastic catheter for forty-eight hours to take care of the post-operative oozing. Again bladder lavage is the exception. The post-operative course of the retropubic case is incomparably easier than any of the other open operations.

Late results.—The end-results of the Freyer are on the whole excellent, but shelf formation does occur in a proportion of cases. Even the excision or punching out of the posterior lip of the bladder neck does not guard against this.

The Harris operation carries its own particular late complications. I have already mentioned in a communication to this Section the truly dreadful post-operative obstruction one meets with occasionally after Harris suturing in which the whole prostatic urethra is strictured. There is also a quota of meatal and other urethral strictures when a relatively large catheter has been employed for ten to fourteen days. Another complication, seldom mentioned, which I find occurs not only in my own cases but in those of other surgeons, is a degree of incontinence lasting for a variable number of weeks. These usually clear up, but I have had to deal with two cases of persistent incontinence from other clinics.

Of the late results of the transurethral resections I must speak at greater length. These operations, loop or punch, have proved of inestimable value in dealing with many types of prostatic obstruction, especially the fibroses. They appeal to the public in that no external cutting is involved, and the hospital stay is short. I can claim, I think, a wider experience of these operations than anyone in this country. I have long been an ardent advocate of their use in the lesser obstructions, the poor risk case, &c., but with a full realization that they had their limitations, or rather should have. The transurethral resection cannot be a complete adenectomy despite claims to the contrary. The bogies of recurrent obstruction and persistent infection are ever present. I have a number of patients now resected more than ten years ago, who have had no further trouble, but other cases have not been so fortunate. I have always admitted this, but felt that in many cases the alternative was unduly hazardous, and that it was better to be alive with the risk of recurrent obstruction than dead, cured. To my mind, the greatest bugbear of resection is the risk of subsequent urethral stricture. Early in my urological career I learned that it was unsafe to pass an unduly large instrument along the male urethra. The commonly used Thompson Punch, euphemistically calibrated 30F, is doing irreparable damage. That the enucleation of a simple tumour should entail such hazardous adventures appeared to me to be a blot on modern surgical achievement. I for one had a sense of frustration; I sought elsewhere. The subpubic operation mentioned by Uteau and Leroy proved impracticable. Noting the excellent exposure of the prostate during the operation of cystectomy, I turned to the retropubic approach. From the very first I have been pleased with this. It is virtually a perineal type of prostatectomy performed well away from the rectum and compressor urethra—the twin bogies of the inferior approach. Moreover, the nerves and arteries of chief moment are situated posteriorly, the anterior aspect of the prostate being accessible without damaging structures other than veins. Anteriorly also the urethra is closest to the surface of the gland, and the ejaculatory ducts are less liable to damage than in the perineal operation. It does not seem to be sufficiently appreciated that the level of the internal meatus is approximately the upper limit of the pubis in the vertical position, and is even higher when there is marked prostatic enlargement and elongation of the prostatic urethra. The retropubic exposure is thus not via a dark, deep, and dangerous hole, as has been suggested by some. The normal anatomy of the approach presents no structures of importance which need be sacrificed. Venous bleeding during the sectioning of the prostatic capsule can be troublesome if adequate care is not taken to deal with these veins, either by ligature or appropriate clamp before division. With the technique I use to-day this bleeding is usually negligible. Three arterial anomalies may be met with, and should be known. I am indebted to my assistant, Mr. Ashton Miller, F.R.C.S., for researches into this subject.

(a) *Accessory pudendal artery*.—This is a sizable vessel which may be met with on the lateral surface of the prostate. According to Buchanan it is only present occasionally, and arises from the intrapelvic portion of the internal pudendal, or from the inferior vesical artery. It passes forward along the lateral aspect of the bladder and prostate to the triangular ligament, which it pierces, branching into deep and dorsal arteries of the penis, and, rarely, the artery of the bulb.

(b) *The dorsal artery of the penis* occasionally arises from the obturator artery close to the entrance of the obturator canal, whence it passes over the posterior aspect of the pubis to reach and pierce the triangular ligament.

These vessels might be injured either during the initial sectioning of the prostatic capsule, or later during the suturing process.

(c) *Aberrant obturator artery*.—This is a better-known anomaly, occurring, according to Gray, in 28% of subjects. It replaces the normal artery, and arises from the deep epigastric of the same side near its origin, passing behind the lacunar ligament, and downwards to the obturator canal. It does not itself lie close to the scene of operation, but the vesical branch normally arising from the obturator artery in the pelvis may spring from this anomalous vessel, and pass via the pubo-prostatic ligament and antero-lateral aspect of the prostate to the bladder.

Now as to the so-called internal sphincter. The classical transvesical procedure entails the division of this structure first with the finger, and later during the delivery of the lateral lobes into the bladder. It is well known that stretching any sphincter entails shock. Moreover, post-operative urethrograms show that in a large proportion of cases the bladder neck remains patulous, and the patient is entirely dependent on the compressor urethrae for continence. Some go a stage further, and fearing a shelf formation due to fibrosis following sepsis, excise or punch out a wedge of trigone, a completely unphysiological

procédure. Some Harris advocates, on the other hand, actually attempt to narrow the bladder outlet, and draw down the trigone into the prostatic bed, so bringing the ureteric orifices almost on to the bladder neck, as seen at subsequent cysto-urethroscopy. In one operation the bladder neck is deliberately enlarged, in the other it is equally deliberately narrowed. Why not leave it alone? This is what one does in the retropubic operation. I must qualify this statement, as when after enucleation of the adenoma one finds the bladder neck sclerotic on palpation, a wedge excision of the neck should be made.

I have repeatedly shown by means of a finger in the bladder where the retropubic procedure has been carried out after a preliminary cystostomy, that the bladder neck is relatively little disturbed even where a large middle lobe, or other intravesical projection, has been removed from below. This is confirmed during one-stage operations, when it is noted that after enucleation there is no escape of urine through the sphincter, yet the stretching of the structure to allow the catheter to pass leads to an escape.

One other point, perhaps of minor importance, is the sexual aspect. It is well known that after the classical prostatectomy, when potency is retained, there is little or no external flow of seminal fluid on ejaculation, apparently owing to lack of competence of the internal sphincter. I have records of two of my retropubic prostatectomies who do ejaculate a reasonable external discharge. In the past I have had several patients who have expressed extreme displeasure at the phenomena observed after a Freyer prostatectomy.

To sum up these considerations, it would appear that the retropubic operation is anatomically the logical one, and that best calculated to remove the obstruction completely, with the least damage to important structures.

Let us consider now the practical aspect, taking in turn the pre-operative care, the actual operative technique, and the after-care. We shall later review results, comparing those obtained by other methods.

In considering pre-operative care I am not unmindful that there is no unanimity as to handling of the various types of case met with. I shall give briefly my own practice:

(a) Case with marked prostatic symptoms, uninfected urine, no great clinical residuum as evidenced by palpation or percussion, and an enlarged gland on rectal examination: In most of these cases I do not trouble my pathologist with extensive renal function tests, but rely on clinical assessment, blood-urea estimation, and, when possible, intravenous urography. If operation is decided upon, renal function being good and other demonstrable pathology being absent, no urethral instrumentation is employed until the patient is on the operating table, when cysto-urethroscopy is carried out. Decision is then made as to whether resection or prostatectomy is the order of the day, and the appropriate measures performed there and then.

(b) Case of acute retention: Where condition is good and early operation is indicated, suprapubic tapping is sometimes employed for a day or two. In most cases a urethral catheter is used, always combined with sulpha drug therapy and forced fluids. Where urinary excretion, renal function tests, or cardiovascular system are inadequate, the decision is made as to whether to continue with urethral catheter drainage, or to carry out a high cystostomy. In most cases met with in this series catheter drainage has been adequate.

(c) Chronic retention: Here the choice will again lie between urethral catheter and cystostomy. I personally usually rely initially on slow decompression via a catheter for the first twelve to twenty-four hours; later spigoting the catheter and releasing it two-hourly. This I regard as more physiological than keeping the bladder constantly empty. Unless the catheter is not tolerated, I rely on this for seven to ten days, and if the renal function is then not reasonably good, perform a cystostomy. I find, as did Harris, that it is only the exceptional case which does not respond to catheter drainage, but I do not hesitate to carry out cystostomy where indicated.

(d) Cases of gross urinary infection and very poor renal function will almost invariably call for cystostomy: Where the function tests are reasonable, sulphonamides and the urethral catheter will often work wonders with sepsis, and render a one-stage retropubic prostatectomy a safe procedure.

These brief rules are, of course, only approximate, as there are always the exceptions.

Associated urological pathology.—I shall only mention those pathological factors which seem to me to have most bearing on the choice of operation to be advised for the enlarged prostate.

(a) *Vesical calculus.*—Where the stone is a large one associated with much urinary infection, then it should be removed suprapubically and the bladder drained, as I have already mentioned under the heading of gross urosepsis, until the condition, general and

local, warrants a prostatectomy. This may be performed either by the classical Freyer technique, or, as I prefer, by the retropubic route. In the rare case, in which a large stone is found associated with little infection, this may be removed at the time of the retropubic operation, the anterior wall of the bladder being deliberately incised, and subsequently closed in two layers. Where the calculus is smaller, it can be removed by introducing appropriate forceps through the internal sphincter after the enucleation of the prostate. Where the calculus is found in the presence of bladder-neck sclerosis, litholapaxy is carried out at the same time as the endoscopic resection.

(b) *Vesical diverticulum*.—Where a pouch of significant size is associated with prostatic enlargement warranting operation, it has been usually held that the removal of the diverticulum should be carried out as a primary measure, and that after an appropriate period of suprapubic bladder drainage, the prostate dealt with. If a classical transvesical prostatectomy is performed in the presence of a diverticulum there is very great likelihood of a failure of the fistula to close, and the removal of a diverticulum after a previous prostatectomy, where there is a persistent fistula, is a procedure taxing the skill of the most expert. I see no reason why a retropubic prostatectomy carried out in the presence of a diverticulum should not be completely successful. There is no bladder fistula to be persistent, and the minimal amount of bladder infection compared with that in a Freyer would be unlikely to be of serious moment. I have quite recently had the opportunity of performing a retropubic prostatectomy in the presence of a diverticulum, but the case is too recent to report. I do not advocate leaving all such diverticula alone, but there are certainly some of these pouches burrowing deep down under the bladder base whose removal is singularly difficult, and which I feel would be better left alone, merely carrying out a retropubic enucleation of the obstructing gland. The Mayo Clinic workers claim that it is seldom necessary to operate upon vesical diverticula where the removal of the bladder-neck obstruction is effected via the transurethral route. This is a view which has not been universally accepted, but I feel that cases will certainly arise from time to time where the surgeon would feel happier to leave the pouch undisturbed provided he can secure a satisfactory prostatectomy.

(c) *Papillary tumours*.—Each case exhibiting the combination of prostatic obstruction and a papillary growth must be judged on its merits. In general, where the tumour is likely to respond to cystoscopic diathermy, this treatment should be carried out first, using a large electrode through an operating cystoscope. Where it appears necessary to open the bladder to deal with the growth, this should be done as a preliminary measure, and later the gland removed retropubically. Where total cystectomy appears indicated, the problem does not arise.

(d) *Calculus prostatitis*.—The calculous prostate causing marked obstruction, especially when associated with gross infection and impaired renal function, has always been a problem to accepted methods. A one-stage operation is unduly hazardous, and the classical removal as a secondary procedure is not easy. A two-stage retropubic prostatectomy would seem to be the answer to the problem.

Anæsthesia.—Almost any preferred form of anæsthesia may be employed. My preference is for pentothal induction, followed by gas-oxygen or cyclopropane, supplemented by pentothal as required, but never exceeding 1 gramme of the barbiturate. In poor risk cases I utilize an abdominal block, subcapsular infiltration of the prostate, and a very brief cyclopropane or pentothal anæsthesia during the enucleation. A good alternative is caudal plus abdominal block. I dislike spinal analgesia because of its not infrequent unpleasant sequelæ.

Technique.—I have already described fully the steps of the operation,¹ and in the light of subsequent experience have not materially altered the technique. No doubt it can be improved. For the preliminary endoscopic inspection I know no instrument superior to my wide angle vision cysto-urethroscope. It enables us to make a rapid inspection of the bladder for associated pathology, and then assess the intravesical and intra-urethral configuration of the obstruction. Continuous irrigation is, of course, employed. The bladder is emptied, and the endoscope withdrawn. Whilst the operator is changing his gown and gloves the assistant prepares the field, and towels up the patient. Only a short mid-line incision is necessary. The transverse incision which I, like many others, prefer in the Harris operation, has no advantage here. In most of my early cases I employed a standard Harris type of self-retaining retractor. A modification with a movable upper blade is useful. The Harris frame, although apparently cumbersome, has many advantages; it does not tilt, and there are few structures on which catgut, &c., will catch. My modification of the Legueu retractor has the merit of being more rapidly

¹*Lancet*, 1945 (ii), 693.

introduced and removed; it is frequently possible to enucleate the adenoma without removing the retractor, and the flexible upper blade can be depressed by digital pressure.

After exposing the gland I pack 18 in. of 6-in. gauze roll into each lateral recess, i.e. between the lateral aspect of the prostate and the levatores ani. 10 c.c. of 1% procaine, to which 3 minims of adrenaline 1/1000 have been added, are now injected into the gland subcapsularly. This opens up a plane of cleavage, and, I think, helps to minimize bleeding. The three under-running sutures to control the veins are now placed, the ends of the sutures left long, and held with hæmostats. I then make a very short vertical nick through the fascia and true capsule, and insert special L-shaped capsule forceps, one on each side, to clamp any veins not controlled by the stay sutures. A transverse incision is then made, either with a scalpel or the diathermy knife, proximal to the clamps. A T-shaped clamp is then applied to the edge of the proximal flap, controlling the small artery which is usually severed in the mid-line. Three stay sutures are now applied to the proximal flap, one in the mid-line and one at each extremity. The clamps are removed, and any individual veins still bleeding seized with hæmostats and coagulated. The false capsule is then opened with a deep inverted V incision.

This is stripped back off the adenoma, which is also cleared distally and laterally with Devine's chisel-pointed scissors curved on the flat. The urethra is deliberately cut across distal to the lateral lobes, and the latter then enucleated with the right index finger from below upwards. A second finger at this stage of turning the lobes upwards is often useful. It is very rarely necessary to utilize a finger in the rectum. Mechanically the enucleation is far sounder than in the transvesical techniques in that the finger is working at right angles to the urethra, and not in the long axis of a cone. There is no danger of avulsing a strip of membranous urethra. When the lobes have been freed distally and laterally they are delivered into the wound, and held either with the fingers of the left hand or by means of Duval's forceps. The trigone is sponged off the adenomatous mass posteriorly, and the bladder neck off it anteriorly, leaving it free except for a cone of mucosa. This latter is then deliberately cut across distal to the bladder neck. A small pack is now placed in the prostatic cavity, whilst the edges of the false capsule are picked up with Kocher, Allis, or other appropriate forceps. The pack is removed, and whilst the special model sucker nozzle is applied to the prostatic cavity, bleeding vessels are visualized and caught with hæmostats. These are then touched with the diathermy needle. The bladder neck is palpated, and, if sclerotic, a wedge resection is made. A suitable-sized Harris catheter is then passed along the urethra; it is seen entering the prostatic bed. Whilst the assistant opens the internal meatus with the spreader, the catheter is guided into the bladder either with forceps, or with a stilet. The false capsule is then closed with a running suture, utilizing the boomerang needle. Bleeding should now have ceased. The stay sutures are now tied together, mid-line to mid-line, right to right, and left to left, after the upper blade of the retractor has been loosened or removed. The retropubic space is dusted with sulphanilamide powder, and the wound closed routinely with a small corrugated drain down to the suture line. Where the venous ooze has not been adequately controlled, a cigarette drain of gauze is preferred to the rubber drain. (I have had recourse to this three times.) After bilateral vasectomy, the catheter is syringed out with flavine 1/6000, the eyes being suitably adjusted so as to be just within the bladder. The catheter is fixed with silkworm gut sutures to the penis. The whole operation need not exceed half an hour, and is frequently completed in under twenty minutes. 4 oz. of 3.8% sodium citrate solution is left in the bladder, and the catheter spigoted. One hour after the patient returns to bed the spigot is released to verify that the catheter is draining, which being so, it is again spigoted. One hour later the spigot is removed, and the catheter connected via sterile tubing to a Winchester at the side of the bed. Aperients are administered on the second evening, and on the third day the patient is allowed up to use the commode. From the fourth day onwards he gets up to sit in the chair. During the day the catheter is spigoted, and released two-hourly. I repeat that I regard this intermittent filling of the bladder as more physiological than keeping the viscus constantly empty. Only in 1 case in 8 is post-operative syringing of the catheter necessary. The drain is shortened on the second day, and removed, in general, on the third day. The catheter is removed on the fourth or fifth day, unless the procedure has been carried out after a preliminary cystostomy, in which case it is left in ten days. Some suprapubic leakage will occur in a small proportion of cases. It is neglected for twenty-four hours, and, if necessary, a small catheter is replaced until the wound is sound and dry. Where a chronic retention has been present before operation the atonicity of the bladder may lead to a retention; if it does not respond to a parasympathetic stimulant further catheter drainage may be necessary. Twice I have seen a retention follow the removal of the catheter due to spasm in nervous patients; a hypodermic of morphia will relieve this. A sulphur drug is administered routinely for

forty-eight hours before operation, and for five days subsequently, unless contra-indicated. The minimal amount of post-operative infection of the urine is noteworthy, and the rapidity with which the urine becomes clear is in marked contrast with that found after the Freyer technique. All patients report two to three weeks after dismissal from hospital, and it is quite exceptional not to find clear, or only faintly hazy, urine on this visit. Instrumentation is employed only where the urinary stream does not appear adequate.

I have employed both thrombin topical and fibrin foam in the prostatic cavity, but cannot claim that they proved any help, nor indeed are they necessary.

Post-operative Complications

These have been in the main singularly infrequent. The comments of the nursing staff, who have also to deal with prostatectomies handled by the older methods are flattering, and mirror my own views. It is only the exceptional case which requires time-consuming bladder wash-outs; even bedpans are unnecessary.

Reactionary hæmorrhage.—I have as yet met with no case where anything more than a bladder lavage has been necessary.

Secondary hæmorrhage.—This I have had four times. All responded to lavage through a catheter, though in one case a fatal pyelonephritis followed. Suprapubic cystotomy for such a complication has in no instance been necessary.

Pyelonephritis.—2 cases have been met with. In one the patient had just recovered from an attack of pyelonephritis associated with retention due to a very large gland. Prolonged catheter drainage had been employed elsewhere. The patient, a doctor, was very averse to a cystostomy which I recommended, and against my better judgment I performed a one-stage retropubic prostatectomy. The immediate post-operative course was completely uneventful. The catheter was removed on the sixth day, and easy voiding followed. On the tenth day pyrexia set in, which failed to respond to sulphanilamides, penicillin, &c., and he succumbed to a recurrence of his pyelonephritis. He was 76, and an admittedly poor risk. In the other case I have no excuse to offer. He was an apparently fit man of 55. The enucleation was not easy, as a subtrigonal nodule had to be dissected from the bed, in addition to large lateral lobes. Secondary hæmorrhage occurred on the sixth day, as mentioned earlier, which responded to bladder lavage, but a pyelonephritis developed later, and he succumbed on the eighteenth post-operative day.

Post-operative urinary leakage.—This will occur in a small number of cases. I feel that, provided the closure of the cavity has been satisfactory, this is due to too early absorption of the catgut. In one case this was clearly demonstrated. The catheter slipped out twenty-four hours after operation, and the house surgeon was unable to attend to the patient for some three hours. During this time urine was voided easily twice, and without leakage. The catheter was replaced, but on its removal on the sixth day, urine escaped from the wound. I now employ No. 1 chromicized catgut for the capsular repair. Every effort must be made to secure a watertight closure of the prostatic cavity; it makes for easy post-operative course, and early dismissal.

Post-operative stricture.—It is obviously too early to comment on this. In 3 cases seen at the first check-up after dismissal the urinary stream was not full, and steels were passed. In all there was some gripping at the bladder neck. A timely dilatation at this stage of soft infiltration will save trouble later.

Pulmonary embolus.—I have as yet met with no case. I attribute this largely to the short period of confinement to bed.

Femoral thrombosis.—The only case I have had was the first in the series already reported, where gross urinary infection preceded the operation due to three years' self-catheterization.

Post-operative fistula.—Despite the armchair fears of some on this score, this has not occurred, nor do I see why it should.

Incontinence.—No case of even temporary incontinence, partial or complete, has been met with. The preservation of both sphincters should render such a possibility very remote.

Clot retention.—I am informed that the armchair detractors of the retropubic procedure hold this as a dread and likely complication. Let me answer them here and now that I have not met it in a form not easily handled through the catheter. I admit that it remains a real possibility, as after any prostatic operation yet described. Should this occur, and the bladder be already opened, the situation is more easily taken care of, but dealing with such an occurrence after a retropubic operation should not be outside

introduced and removed; it is frequently possible to enucleate the adenoma without removing the retractor, and the flexible upper blade can be depressed by digital pressure.

After exposing the gland I pack 18 in. of 6-in. gauze roll into each lateral recess, i.e. between the lateral aspect of the prostate and the levatores ani. 10 c.c. of 1% procaine, to which 3 minims of adrenaline 1/1000 have been added, are now injected into the gland subcapsularly. This opens up a plane of cleavage, and, I think, helps to minimize bleeding. The three under-running sutures to control the veins are now placed, the ends of the sutures left long, and held with hæmostats. I then make a very short vertical nick through the fascia and true capsule, and insert special L-shaped capsule forceps, one on each side, to clamp any veins not controlled by the stay sutures. A transverse incision is then made, either with a scalpel or the diathermy knife, proximal to the clamps. A T-shaped clamp is then applied to the edge of the proximal flap, controlling the small artery which is usually severed in the mid-line. Three stay sutures are now applied to the proximal flap, one in the mid-line and one at each extremity. The clamps are removed, and any individual veins still bleeding seized with hæmostats and coagulated. The false capsule is then opened with a deep inverted V incision.

This is stripped back off the adenoma, which is also cleared distally and laterally with Devine's chisel-pointed scissors curved on the flat. The urethra is deliberately cut across distal to the lateral lobes, and the latter then enucleated with the right index finger from below upwards. A second finger at this stage of turning the lobes upwards is often useful. It is very rarely necessary to utilize a finger in the rectum. Mechanically the enucleation is far sounder than in the transvesical techniques in that the finger is working at right angles to the urethra, and not in the long axis of a cone. There is no danger of avulsing a strip of membranous urethra. When the lobes have been freed distally and laterally they are delivered into the wound, and held either with the fingers of the left hand or by means of Duval's forceps. The trigone is sponged off the adenomatous mass posteriorly, and the bladder neck off it anteriorly, leaving it free except for a cone of mucosa. This latter is then deliberately cut across distal to the bladder neck. The stay sutures are now tied together, mid-line to mid-line, right to right, and left to left, after the upper blade of the retractor has been loosened or removed. The retropubic space is dusted with sulphanilamide powder, and the wound closed routinely with a small corrugated drain down to the suture line. Where the venous ooze has not been adequately controlled, a cigarette drain of gauze is preferred to the rubber drain. (I have had recourse to this three times.) After bilateral vasectomy, the catheter is syringed out with flavine 1/6000, the eyes being suitably adjusted so as to be just within the bladder. The catheter is fixed with silkworm gut sutures to the penis. The whole operation need not exceed half an hour, and is frequently completed in under twenty minutes. 4 oz. of 3.8% sodium citrate solution is left in the bladder, and the catheter spigoted. One hour after the patient returns to bed the spigot is released to verify that the catheter is draining, which being so, it is again spigoted. One hour later the spigot is removed, and the catheter connected via sterile tubing to a Winchester at the side of the bed. Aperients are administered on the second evening, and on the third day the patient is allowed up to use the commode. From the fourth day onwards he gets up to sit in the chair. During the day the catheter is spigoted, and released two-hourly. I repeat that I regard this intermittent filling of the bladder as more physiological than keeping the viscus constantly empty. Only in 1 case in 8 is post-operative syringing of the catheter necessary. The drain is shortened on the second day, and removed, in general, on the third day. The catheter is removed on the fourth or fifth day, unless the procedure has been carried out after a preliminary cystostomy, in which case it is left in ten days. Some suprapubic leakage will occur in a small proportion of cases. It is neglected for twenty-four hours, and, if necessary, a small catheter is replaced until the wound is sound and dry. Where a chronic retention has been present before operation the atonicity of the bladder may lead to a retention; if it does not respond to a parasympathetic stimulant further catheter drainage may be necessary. Twice I have seen a retention follow the removal of the catheter due to spasm in nervous patients; a hypodermic of morphia will relieve this. A sulpha drug is administered routinely for

(f) *Sexual sequelæ*.—In no other operation with which I am acquainted is the phenomenon of external ejaculation noted afterwards, excluding, of course, minimal resections.

Here are the facts and figures of my experience with this operation. Including every case of prostatic obstruction admitted to my wards and private beds during the period since August 26, 1945, when I performed my first retropubic prostatectomy, I have dismissed 1 case wearing a suprapubic tube (blood urea over 200 despite prolonged drainage), have performed 1 Freyer enucleation (in private, early in the series). 1 patient was admitted moribund with retention and advanced uræmia, and succumbed six hours later without my ever having seen him. Another case, admitted with severe spontaneous prostatic hæmorrhage and clot retention, was subjected to cystostomy. The following table will indicate the procedures carried out in the remainder:

One-stage retropubic prostatectomy	74 cases
Two-stage retropubic prostatectomy	{ cystostomy elsewhere	7 cases
	{ cystostomy by me	3 cases
Endoscopic resection	4 cases
Retropubic evacuation of prostatic abscess	1 case
Suprapubic cystostomy (awaiting second stage)	2 cases

In conclusion, I commend with every confidence this operation as a sound rational procedure, the practical results of which bear out the obvious theoretical advantages. It may be carried out either as a one-stage procedure, or after preliminary cystostomy, and in my view it is the procedure of choice in every case affording a reasonable operative risk, excluding the fibroses, where endoscopic resection holds the field.

Many of you have, I know, performed the operation, and I look forward to hearing of your experiences, and, no less, the criticisms of others still faithful to the older methods.

The President: In opening this discussion my chief duty, and a very pleasant one, is to say how privileged I feel to be here to-night and how grateful we are to Mr. Millin for his admirable review of prostatectomy up to date and lucid description of this new addition.

In prostatic hypertrophy the genital pedestal swells and strangulates the urethral exit beneath the urinary chamber. Mr. Millin makes a direct attack on the obstacle and saves adding surgical injury to a bladder which has long suffered pathological insult. This struck me as a bold strategic move in prostatectomy when first he shared his new retropubic operation with the Royal Society of Medicine last November. The intact bladder is ready for action when the artificial drainage is removed. The post-operative course is correspondingly easier than that following the transvesical route, but has its complications. The packing of fat in the spaces round the bladder neck is favourable soil for sepsis and has for long made the cave of Retzius a place of evil repute. Throwing tradition aside, however, Mr. Millin elects to approach the prostate through it. Has the region been malignised? Parietal sepsis has certainly been the rule rather than the exception in my 8 cases, though the discharge of pus has been but transient. The resumption of natural micturition following withdrawal of the catheter whether early, fourth day, or as late as the tenth post-operative day has in several proved a time of distress and anxiety. The patient appears liable to spasm like a veritable vesical crisis which in 1 case needed suprapubic puncture for its relief. Considerable negotiation may be needed to coax the tip of sound or catheter into the bladder.

But the risk of a more subtle form of post-operative obstruction attends this operation and led to the second of the two fatalities among my series. An elder of 79 years and a chronic bronchitic, died suddenly of pulmonary embolism when healed and ready for home. In the second fatality, the patient had trouble after removal of the catheter on the eighth post-operative day. The house surgeon reinserted the catheter. It did not function well, there was increasing uræmia and urinary output was fitful and finally appeared to cease. Post-mortem revealed a stagnant bladder with about 12 oz. of purulent urine pent up by a pair of apposed vesical "tonsils" overlying the outlet of the bladder and consisting of adenomatous prostatic remains! These fatal relics of the prostate were evidently growing semi-detached from the main subvesical mass and it was easy for such to escape the sweep of the enucleating finger. The moral is to palpate the lining of the prostatic cavity for buried nodules and pass the finger round inside the bladder neck in doubtful cases.

One of the advantages of such total enucleative operations as Mr. Millin's over the resecto-punch method of prostatectomy lies in the completeness of removal and consequent good hope of cure in cases of "enclosed" cancer unsuspected before or during operation.

Mr. R. Ogier Ward stressed the fact that the operation should not be described as an easy one. Once the surgeon was committed to it he must continue and complete it. It was not possible to stop and be content with bladder drainage.

Mr. E. W. Riches: A discussion of the results of the new operation would be premature at this stage. There are two sound principles involved in its performance, a direct approach to the site of disease, and enucleation of the prostate from below starting at the lower borders of the lateral lobes. This latter principle has also been stressed by Harris and prevents the removal of a tube of urethral mucous membrane below the verumontanum which is one of the causes of post-operative stricture. Regarding details it is unfortunate that a very vascular area has to be traversed; if the incision in the false capsule is made

the scope of any surgeon embarking on this form of surgery. Few clot retentions fail to respond to the aspiration technique, provided a suitable catheter and syringe are to hand. If this should fail, it would only be necessary to remove the uppermost two sutures in skin and aponeurosis, plunge a knife into the bladder, evacuate the clots with a sponge forceps, and leave in a suitable drainage tube. This procedure could be performed without even removing the patient from his bed. If the situation should arise after the wound is healed, anaesthesia might be required to reopen the uppermost part of the wound. I repeat I have not experienced it in over 80 cases.

Mortality.—Amongst these 85 cases I have had 4 deaths—2 from pyelonephritis already mentioned, and 2 from cardiac failure within forty-eight hours of operation. In 2 of these 4, I operated against my better judgment, each refusing a preliminary cystostomy. Representing as this does a continuous series, and an initial one at that, I am confident that even better figures will be forthcoming. The first death incidentally was in the thirty-first case. This is admittedly too small a number from which to quote mortality rate. For what it is worth, it represents under 5%.

Operative Difficulties

Anatomical anomalies.—These have already been described, and could conceivably prove troublesome if the operator were not aware of their presence, and on the look-out. I have met with only one abnormal artery—a deep penile branch from the obturator. It was clearly seen when the prostate was exposed, and was doubly clamped, cut, and diathermized.

In one case, a very large irreducible scrotal hernia made exposure of the prostate on that side none too easy, but the enucleation of a 127 grammes gland was effected successfully.

In another case, the removal of a very adherent fibro-adenomatous gland, associated with a thin-walled bladder, led to a tearing of the anterior fibres of the sphincter. These were sutured.

Second-stage prostatectomy.—I have found no particular difficulty in carrying this out, and I regard it as preferable to a Freyer enucleation where a previous cystostomy has been performed, even in cases where the fistula has been established adjacent to the pubis. Where the opening is low, I make a transverse incision, partially dividing the tendons of the recti; otherwise, a vertical mid-line incision downwards from the fistula. The adherence is merely at the muscle level, and the retropubic space opens up readily to expose the prostate. The enucleation and suturing of the capsule are routine. The bladder fistula is then closed. No extensive dissection of the track is necessary. The mucous membrane is freed and inverted with a pursestring. The aponeurosis is approximated superficially, and the skin closed. The whole procedure need not take more than thirty minutes. My reason for performing a retropubic prostatectomy as a secondary procedure in preference to the more expeditiously carried out Freyer enucleation is that I believe it is more benign—there is less shock, less post-operative bleeding, less post-operative discomfort, less risk of persistent fistula, and a more speedy dismissal from hospital. I believe that the extra ten to fifteen minutes on the operating table are well spent.

Finally, let us compare the retropubic operation with other accepted techniques.

(a) *Technically* the operation is far easier to master than either the perineal or transurethral. It is no more difficult than the Harris, and though admittedly not an operation for the occasional prostatectomist, as is the Freyer, should be well within the scope of the trained general surgeon.

(b) *Mortality.*—Preliminary experiences indicate that the risk should be less in this operation than in any other, excluding perhaps the transurethral. The demerits of the latter in the grosser hypertrophies have already been indicated.

(c) *Post-operative course.*—This appears to be easier for both patient and surgeon than in any rival procedure. Indeed, one of the most striking features of the operation is the almost complete freedom from pain. The spasms common in the Freyer operation are not seen.

(d) *Hospitalization.*—This is in general far shorter than in any other open operation.

(e) *Long-term result.*—It is too early to comment on this, but I see no reason to believe that the results should be inferior to those obtained by any transvesical approach. They are without doubt better than those obtained perineally, and by virtue of the completeness of the operation, should certainly transcend the transurethral.

In the other case, there were five medium-sized stones in the bladder. It had been my intention to deal with these through a separate incision in the bladder wall. I found, however, that it was easy to feel the stones on passing a finger through the internal meatus and so I extracted them through this route, thereby, I think, unduly stretching the bladder neck. Urinary leakage occurred on the fourth day and this soon became obviously infected. Twelve days after the operation, an abscess appeared over the gluteal region, which had to be evacuated.

These incidents do not detract from the merits of the operation, but rather serve to emphasize the necessity of adhering to the technique described by Mr. Millin. It is of importance to make certain that the catheter has been properly inserted into the bladder and that it does not become displaced whilst completing the operation.

The operation is perhaps technically more difficult than the suprapubic method, but can, nevertheless, be expeditiously accomplished. When the operation is completed, the after-treatment is simple and no specially trained team is required to carry it out.

Mr. Clifford Morson (*in absentia*, read by Mr. Ainsworth-Davis): There seem now to be almost as many techniques for prostatectomy as there are urologists in this country. The explanation is simple. Surgeons are dissatisfied with many of the end-results, and it is not to be wondered at when it is remembered how much damage is done to the urethra by the removal of the prostate. Surgery can never be the last word in the treatment of this disease. It is dangerous to dogmatize about the results of a new operation until it has had a fair trial, but I certainly like the simplicity and minimum of damage to surrounding tissues of Mr. Millin's technique. However, I cannot give whole-hearted support to it until I know what are going to be its remote results, and for this we must wait two years. In a ward of one of my hospitals there lie side by side suprapubic and retropubic cases. The only difference in the post-operative convalescence is the anxiety about the tied-in catheter blocking with a closed bladder. As for length of stay in hospital both are healed in about a fortnight, but he is a foolish surgeon who hurries his prostate cases out of hospital. I would remind you of the investigations of Semple and myself some years ago which showed that the rate of healing in the prostatic cavity was extremely slow, and many weeks after the abdominal wound had healed there was a raw surface. The extent of that raw area is reduced by a plastic operation such as Wildbolz's or Harris'. Now that is what affects the remote results. The more scar tissue there is uniting bladder mucous membrane to urethral mucous membrane the more urinary dysfunction there will be. Scar tissue contracts slowly so that the dysfunction may not manifest itself for a long time. I think that like the suprapubic operation, the retropubic will give good immediate results. An amazing change has come over the results of suprapubic prostatectomy in the last five years thanks to the complete control of bladder sepsis. Secondary hæmorrhage now is very rare.

Electrolytic sodium hypochlorite, the sulpha drugs, urea formic iodide, and now penicillin are all playing their part in reducing complications and the mortality rate. Professor Noordenbos of Amsterdam in a recent speech at the College of Surgeons stated that the introduction of penicillin had caused the greatest revolution in surgery since Lister. There is no reason to-day why any prostatectomy case in private practice should die of a urinary complication. In my last 40 cases in private practice I have not had a death. For the past 2 years I have had 60 cases at a municipal hospital with 2 deaths. It is notorious that many of these patients are poor surgical risks and yet they survive the operation. Mr. Irwin at St. Paul's is getting similar results.

Mr. Alex. E. Roche: The main advantages of Mr. Millin's operation are not its low mortality or the short period in bed—about two weeks. Similar advantages are claimed for perurethral resection and for Steinach II, which both have this advantage over Millin's operation, of avoiding a suprapubic incision.

Nor is the absence of suprapubic leakage of urine the main advantage of this operation. That, again, is shared by the perurethral resection and Steinach II, not to mention Harris's prostatectomy with closure.

No, the main advantage, it seems to me, is that, unlike perurethral resection and Steinach II, Millin's operation is radical.

The absence of mortality in 20 cases is good, but, of course, we all have runs of 20 or more prostatectomies without mortality. Personally I like to have, and I think I can achieve, a low mortality in my prostate operations—perhaps 5 to 7%. I do a two-stage Freyer-like prostatectomy—an operation which will, I think, last as long as prostatectomies are being performed.

With regard to nomenclature all suprapubic operations are retropubic when the patient is supine, but, whereas ordinary suprapubic prostatectomy is transvesical, Millin's is prevesical, so I prefer the term prevesical prostatectomy to retropubic prostatectomy.

Mr. John Everidge: I think too much has been said about spasms arising as the direct result of incision through the bladder wall. After all we do not see spasms after simple suprapubic drainage nor after partial cystectomy, &c., in either sex. A further factor must be necessary.

Mr. F. E. Feilden: In my view there is no one approach to the pathological prostate; each case must be considered on its own merits, and the appropriate route selected after careful pre-operative investigation. I do not think the post-operative pain referred

vertical fewer vessels are divided, but even so it is a bloody operation, although there is little bleeding from within the prostatic cavity. I do not like the preputial stitch and prefer to anchor the catheter by a sling stitch passed through the fundus of the bladder to a button on the abdominal wall. The catheter is the weak point of the operation as it is in the original Harris procedure, the danger being urethritis. In eight cases there has been one of œdema of the penis and urethritis, and this patient had a secondary hæmorrhage with clot retention on the ninth day; it was relieved by catheterization and glycerin of pepsin. Cysto-urethroscopy has been done in all my cases between the ninth and the nineteenth post-operative day, and it invariably showed some sloughs in the prostatic urethra or at the bladder neck. I do not think therefore that patients should be discharged in a fortnight, I prefer to keep them in for three weeks.

A urethral catheter for preliminary drainage carries the same danger, but suprapubic catheterization makes a two-stage operation quite possible if the catheter is placed high, and four of my cases have been so treated. I prefer a transverse skin incision.

As compared with the Harris operation the approach is more difficult but the reconstruction easier. There appears to be little difference in the final results but the immediate convalescence is smoother after the retropubic operation owing to the absence of bladder spasms. The future development of the operation lies in the possibility of reducing the period of urethral catheter drainage.

Mr. H. K. Vernon: I have performed the operation on 13 cases, so far without mishap. From this limited experience I am as yet unconvinced that it is the operation of choice as a second stage procedure. One of my difficulties has been oozing from branches of the dorsal vein of the penis due, no doubt, to faulty placing of the ligature and injury of the veins by the boomerang needle. In the last case I decided to perform the operation without preliminary ligature of the vein, but the bleeding after incising the capsule was more than in the other cases. The operation is completed more quickly if the bleeding from the plexus is largely ignored until after the prostate is enucleated. Hæmorrhage is then easily controlled.

Mr. Arthur Jacobs: Since Mr. Millin described his operation, I have performed retropubic prostatectomy on 19 occasions. I well realize that such a limited series carried out in a period of under two months is of no value as a basis for any statistical study, but it has provided me with sufficient experience of the operation to enable me to say that I believe the claims made for it by Mr. Millin are justified. Occasional difficulties and complications, however, do arise.

My patients represented the usual cross-section of prostatic cases with varying degrees of cardiovascular and renal impairment and 3 were in the age-group 70 to 77. Of the 19 cases, I had 1 death, the circumstances of which I shall describe to you shortly. 16 of the patients had an uneventful recovery. Some urinary leakage occurred in 3 of these, which, however, ceased spontaneously in fourteen, sixteen and twenty-one days respectively. All were up on the fourth or fifth day and with the exception of these 3 cases and not counting, of course, those operated on in recent days and still under my care, were able to go home in twelve to sixteen days. One of the patients had a persistently blood-stained urine throughout the period of post-operative catheter drainage and, on removing the catheter, was unable to void urine. On passing a gum-elastic catheter, a collection of small clots was evacuated by suction with a syringe. The catheter was tied in for twenty-four hours and there was no further trouble. That was the only incident of bleeding; it was not serious and was easily dealt with.

The one mortality occurred with my eighth case. The patient was a man of 64, with a retention of ten days' duration, which his doctor had been relieving by catheterization. There was a history of previous cardiac trouble and an increased cardiac dullness with a rough murmur at the aortic area were present. The hæmoglobin was 48% and the R.B.C. just over 3½ millions. His blood urea on admission was 110 mg.% and intravenous urography carried out after a few days' catheter drainage and forced diuresis showed moderate dilatation in the right pelvis and calices and marked dilatation on the left side. After eleven days' catheter drainage, by which time his blood urea had fallen to 56 mg.% and his secondary anæmia had improved with coliron and anahæmin, operation was proceeded with and was easily accomplished within thirty-five minutes. On proceeding to place the retention stitch and irrigate the catheter, it was found that the latter was not in the bladder. It had either become displaced or had not been properly inserted and all efforts to replace it failed. I was finally compelled to pass a metal catheter, which was the only type I could guide into the bladder and tied this in. About twenty minutes were occupied with these manœuvres and, by the end of that time, the patient had become quite markedly shocked. He failed to respond to plasma infusion and other supportive treatment and died seven hours after the operation. I feel that if this trouble with the catheter had not occurred, the patient, though not a good operative risk, would almost certainly have come through successfully.

There were complicating incidents with two other cases. In one, this was again the result of the catheter becoming displaced from the bladder. Profiting from my previous experience, when I found it could not be immediately replaced, I reopened the abdominal wound and inserted a Malecot tube into the bladder. The tube was delivered through the lower extremity of the incision and the wound resutured. It was interesting to observe that although some 6 oz. of flaving had been instilled through the catheter, none of it had permeated through the sutured prostatic capsular layers. On the removal of the suprapubic tube ten days after operation, normal voiding was gradually resumed and the patient left hospital on the twenty-eighth post-operative day. Final closure of the sinus followed the insertion of a catheter, which was passed into the bladder without difficulty and retained for three days.

In the other case, there were five medium-sized stones in the bladder. It had been my intention to deal with these through a separate incision in the bladder wall. I found, however, that it was easy to feel the stones on passing a finger through the internal meatus and so I extracted them through this route, thereby, I think, unduly stretching the bladder neck. Urinary leakage occurred on the fourth day and this soon became obviously infected. Twelve days after the operation, an abscess appeared over the gluteal region, which had to be evacuated.

These incidents do not detract from the merits of the operation, but rather serve to emphasize the necessity of adhering to the technique described by Mr. Millin. It is of importance to make certain that the catheter has been properly inserted into the bladder and that it does not become displaced whilst completing the operation.

The operation is perhaps technically more difficult than the suprapubic method, but can, nevertheless, be expeditiously accomplished. When the operation is completed, the after-treatment is simple and no specially trained team is required to carry it out.

Mr. Clifford Morson (in *absentia*, read by Mr. Ainsworth-Davis): There seem now to be almost as many techniques for prostatectomy as there are urologists in this country. The explanation is simple. Surgeons are dissatisfied with many of the end-results, and it is not to be wondered at when it is remembered how much damage is done to the urethra by the removal of the prostate. Surgery can never be the last word in the treatment of this disease. It is dangerous to dogmatize about the results of a new operation until it has had a fair trial, but I certainly like the simplicity and minimum of damage to surrounding tissues of Mr. Millin's technique. However, I cannot give whole-hearted support to it until I know what are going to be its remote results, and for this we must wait two years. In a ward of one of my hospitals there lie side by side suprapubic and retropubic cases. The only difference in the post-operative convalescence is the anxiety about the tied-in catheter blocking with a closed bladder. As for length of stay in hospital both are healed in about a fortnight, but he is a foolish surgeon who hurries his prostate cases out of hospital. I would remind you of the investigations of Semple and myself some years ago which showed that the rate of healing in the prostatic cavity was extremely slow, and many weeks after the abdominal wound had healed there was a raw surface. The extent of that raw area is reduced by a plastic operation such as Wildbolz's or Harris'. Now that is what affects the remote results. The more scar tissue there is uniting bladder mucous membrane to urethral mucous membrane the more urinary dysfunction there will be. Scar tissue contracts slowly so that the dysfunction may not manifest itself for a long time. I think that like the suprapubic operation, the retropubic will give good immediate results. An amazing change has come over the results of suprapubic prostatectomy in the last five years thanks to the complete control of bladder sepsis. Secondary hæmorrhage now is very rare.

Electrolytic sodium hypochlorite, the sulpha drugs, urea formic iodide, and now penicillin are all playing their part in reducing complications and the mortality rate. Professor Noordenbos of Amsterdam in a recent speech at the College of Surgeons stated that the introduction of penicillin had caused the greatest revolution in surgery since Lister. There is no reason to-day why any prostatectomy case in private practice should die of a urinary complication. In my last 40 cases in private practice I have not had a death. For the past 2 years I have had 60 cases at a municipal hospital with 2 deaths. It is notorious that many of these patients are poor surgical risks and yet they survive the operation. Mr. Irwin at St. Paul's is getting similar results.

Mr. Alex. E. Roche: The main advantages of Mr. Millin's operation are not its low mortality or the short period in bed—about two weeks. Similar advantages are claimed for perurethral resection and for Steinach II, which both have this advantage over Millin's operation, of avoiding a suprapubic incision.

Nor is the absence of suprapubic leakage of urine the main advantage of this operation. That, again, is shared by the perurethral resection and Steinach II, not to mention Harris's prostatectomy with closure.

No, the main advantage, it seems to me, is that, unlike perurethral resection and Steinach II, Millin's operation is radical.

The absence of mortality in 20 cases is good, but, of course, we all have runs of 20 or more prostatectomies without mortality. Personally I like to have, and I think I can achieve, a low mortality in my prostate operations—perhaps 5 to 7%. I do a two-stage Freyer-like prostatectomy—an operation which will, I think, last as long as prostatectomies are being performed.

With regard to nomenclature all suprapubic operations are retropubic when the patient is supine, but, whereas ordinary suprapubic prostatectomy is transvesical, Millin's is prevesical, so I prefer the term prevesical prostatectomy to retropubic prostatectomy.

Mr. John Everidge: I think too much has been said about spasms arising as the direct result of incision through the bladder wall. After all we do not see spasms after simple suprapubic drainage nor after partial cystectomy, &c., in either sex. A further factor must be necessary.

Mr. F. E. Feilden: In my view there is no one approach to the pathological prostate; each case must be considered on its own merits, and the appropriate route selected after careful pre-operative investigation. I do not think the post-operative pain referred

to by Mr. Millin is associated with either the indwelling catheter or the line of suture, but is due to incomplete hæmostasis.

The operation of retropubic prostatectomy is not one which should be done by the occasional prostatectomist. We all know of the appalling results associated with trans-urethral resection when performed by those not competent to do the operation. The same would occur in the operation of retropubic prostatectomy under similar conditions, and much unjustifiable discredit will be brought upon the operation.

Mr. H. P. Winsbury-White: I congratulate Mr. Millin upon his success with a new operation, especially in relation to hæmostasis, which is always a chief concern of every prostatectomist.

I was glad Mr. Millin had mentioned that, following the cystoscopic examination, he was prepared to proceed at once to either transurethral resection or prostatectomy, according to what he found. I, too, feel that this is a wise way to proceed, because there are certain cases in which the decision can only be arrived at by cystoscopy.

I cannot agree that it is not necessary to remove vesical diverticula. If these are left behind then infection of the bladder will remain, whereas one can look forward to a crystal-clear urine in due course for the majority of cases.

The question of post-operative obstruction is a real one with all types of prostatectomy, and I would like to know from Mr. Millin whether it is possible to remove the posterior margin of the prostatic bed by the retropubic route. I, personally, remove this shelf with the diathermy knife and feel that this procedure is an important safeguard.

Mr. Edgar Freshman asked whether Mr. Millin had found it helpful to use a special posterior blade with one of the standard automatic bladder retractors.

Mr. Millin (in reply): I take this opportunity of expressing my gratification at the reception accorded by so many urologists, not only here to-night but in correspondence from many parts of the world, to my retropubic operation. I had been prepared for more opposition. To the President I would say that the "subtle" form of post-operative obstruction he has met with so disastrously indicates no inherent fault of the operation but rather faulty technique—obviously careful inspection and palpation of the prostatic bed had not been carried out.

I do not agree with Mr. Riches that the vertical incision through the capsules is preferable in the case of the grosser enlargements; it may lead to an upward or downward splitting, so jeopardizing either internal or external sphincter. I still prefer the simple preputial suture for catheter fixation to one traversing the bladder. Unless extensive diathermic coagulation has been employed, cysto-urethroscopy on the eleventh post-operative day shows few if any sloughs, and discharge from hospital on the fourteenth day is safe. I agree with him on the desirability of minimizing the period of indwelling catheter and now aim to remove the tube on the third or fourth post-operative day.

On the question of post-operative spasms, I agree with those who believe that these are primarily due to clots in the bladder and I attribute the freedom from this complication in the operation to the absence of this factor.

To Mr. Winsbury-White I would say that it is simple and frequently desirable to resect a wedge from the posterior lip of the bladder neck in the retropubic approach.

Special instruments are not an essential, but a movable upper blade to the self-retaining retractor is a help.

Observations on the Value of Electromyography in Lesions Involving the Lower Motor Neurone in Man

By GRAHAM WEDDELL, M.D.

In a previous communication to the Neurological Section of the Royal Society of Medicine (Weddell, 1943), a brief account was given of the technique and application of electromyography in clinical medicine. Since then, many more neurological affections have been investigated, as a result of which it has become possible to indicate more precisely the value of electromyography in the diagnosis and prognosis of lower motor neurone lesions.
